### Editorial

The In modern manufacturing, the product architecture design options are usually restricted to those that can be produced with 100% confidence using those proven technologies to satisfy the existing customer requirement. As a result, the inefficiencies of architecture design are considerable due to such limitations. This issue is of particular interests in cyber manufacturing when exploring the trade off between generality and feasibility in product design and manufacturing. It can be expected that the improvement and extension of the existing product architecture may be required to meet new customer requirement when new technologies become available. An effective system performance assessment algorithm is necessary to facilitate the extension of existing product architecture. Though there has been a lot of research on architecture assessment, there is no well-defined model for level by level architecture assessment considering architecture extension. In this paper, we propose a general architecture assessment model considering the integration of additional functionality requirements and performance metrics to evaluate the architecture performance along its value pathway to meet stakeholder's requirements. A numerical case study focusing on a hypothetical auto cooling system is used to validate the effectiveness of the proposed model [1,2].

Characterizing a total engineering and setting up a suitable relationship network among all useful boundaries of a specific item assume a basic part in settling framework fluffiness for building an effective item design. The design building focusing on esteem creation normally starts from the need or useful prerequisites of the partners. Since esteem is benefit at cost, it is vital to adjust the framework intricacy also execution capacities of the item engineering. The necessary framework abilities to accomplish the given objective are called key execution ascribes (KPA's). To satisfy those KPA's, the arrangement explicit capacity, or the top usefulness that is utilized to assemble the engineering, is deteriorated into lower level functionalities. By recursively applying the capacity objective thinking, all more elevated level capacities can be disintegrated down to the sensible granulation [3-5].

The most elevated level useful boundaries in the disintegration are called proportion of adequacy (MOEs). Still up in the air by the connections to and execution of the quick lower level utilitarian boundaries which are characterized as proportion of execution (MOPs). Those MOPs are the resultant of other even lower level practical boundaries called specialized execution measures (TPMs). With the fast headway of advances lately, the models of the present items have become intrinsically intricate. It for the most part comprises of exceptionally interrelated, interconnected, or intertwined substances. Furthermore, due to the pattern of looking for the best worth of item and bettering life at least expense with most extreme fulfillment, this complex design should be changed or stretched out constantly to track down new upper hands in quickly evolving market [6, 7].

The engineering expansion can be acknowledged either by adding new utilitarian necessities to the current design or then again acquainting new measurements with measure extra execution of the engineering. On one hand, to accomplish new practical necessities, the extra capacities should be separated down to the sensible granulation

like existing design. Then, at that point, it is needed to connect recently created useful boundaries with any remaining existing ones at each level of the design. The presentation of the drawn out framework relies upon the impact of inner connection among all practical boundaries in the drawn out design. Then again, when new execution metric is required, the presentation of new measurement for each useful boundary at each level along its worth pathway can gauge the framework capacity of new engineering [8].

Despite the fact that expansion of existing engineering in item configuration is progressively significant in the present serious world, research that can be utilized to guide such an expansion and survey the presentation of post-augmentation has been less engaged. Most existing writing in engineering demonstrating for configuration is centred around the appraisal of high level ascribes explicitly founded on KPA's. For instance, depicted an assessment strategy for evaluating a reach of arrangement of frameworks (SoS) meta-design options by characterizing the fluffy ideas and setting up rule sets for the general SoS. Renault introduced an evaluation model explicitly for automated flying vehicle (UAV) frameworks. This model surveys the likelihood of produced design meeting execution just as capacity prerequisites. Produced a proper portrayals of a distinct framework design and showed how these portrayals can be utilized to assess a started up framework engineering to decide if it is very much framed or not introduced a fluffy rationale based technique for Failure Mode and Effect Analysis for quality confirmation and dependability improvement, interdependencies among different disappointment modes with unsure proposed a methodology for the determination of elective models in an associated framework to expand flexibility of the general foundation framework. Renault and Dagli portrayed an incorporated strategy to survey SoS meta-design using the hereditary calculation enhanced KPA's and the Mamdanitype rule based fluffy derivation framework. Likewise, Renault illustrated double use of rule based fluffy deduction [9,10].
