Abstract

Dyshormonogenetic goiter is a rare cause of congenital hypothyroidism occurring due to a lack of enzymes necessary for the synthesis of thyroid hormones. It is morphologically characterized by architectural and cellular pleomorphism that may mimic thyroid malignancy and cause difficulties in differential diagnosis.

We report a new case occurring in a 37-year-old male with history of hypothyroidism since the age of 6 years treated by L-thyroxin. He developed a progressively slow growing multinodular goiter and consulted for recent dyspnea. Computed tomography scan showed a multinodular plunging goiter with compression of the trachea and vessels in the left side. A total thyroidectomy was performed.

Gross examination revealed an enlarged and multinodular thyroid gland, presenting hemorrhagic changes in the larger nodules. Histologically, the features were consistent with dyshormonogenetic goiter.

The literature on the histopathology of dyshormonogenetic goiter is reviewed and clues to avoid inappropriate overdiagnosis of malignancy are given.

Keywords: Goiter; Dyshormonogenetic; Pathology; Surgery; Hypothyroidism

Introduction

Dyshormonogenetic goiter (DG) is a rare entity that affects 1 in 30,000 to 50,000 live births, and it is the second most common cause (10 to 15%) of permanent congenital hypothyroidism [1]. It is a genetically determined thyroid hyperplasia due to an enzyme defect in thyroid-hormone synthesis. It is morphologically characterized by architectural and cellular pleomorphism that may mimic thyroid malignancy and cause difficulties in differential diagnosis.

Case Report

We report a case of a 37-year-old male patient with history of hypothyroidism since the age of 6 years treated by L-thyroxin 800 microgram per day. The patient’s brother had undergone five years ago a thyroidectomy for a multinodular goiter lasting from childhood. He presented with a voluminous multinodular goiter with tracheal compression causing dyspnea. Computed tomography scan showed a multinodular plunging goiter at the right cervicothoracic space coming in contact with the aortic arch with displacement of the trachea and vessels in the left side.

A total thyroidectomy was performed. Gross examination revealed an enlarged and multinodular thyroid gland, presenting hemorrhagic changes in the larger nodules (Figure 1). Histologically, the process was diffuse, without normal thyroid tissue. The nodules were markedly cellular exhibiting a variety of architectural appearances with microfollicular, trabecular and solid patterns (Figure 2). The follicular cells typically exhibited severe cytologic atypia, including bizarre and markedly enlarged, hyperchromatic nuclei (Figure 3). These nuclear changes were most common in the inter nodular areas. There was no capsular or blood vessel invasion. These features were consistent with dyshormonogenetic goiter. The patient feels well one year after.

Discussion

Congenital hypothyroidism is the most common neonatal metabolic disorder and results in severe neurodevelopmental impairment and infertility if untreated. It is usually sporadic, but up to 2% of thyroid dysgenesis is familial, and congenital hypothyroidism caused by organification defects is often recessively inherited. The candidate genes associated with this genetically heterogeneous disorder form two main groups: those causing thyroid gland dysgenesis and those causing dyshormonogenesis [2]. Genes associated with thyroid gland dysgenesis include the Thyroid Stimulating Hormone (TSH) receptor in non-syndromic congenital hypothyroidism, and Gsa and the thyroid transcription factors (TTF-1, TTF-2, and Pax-8), associated with different complex syndromes that include congenital hypothyroidism [2,3].

Dyshormonogenetic goiter (10 to 15% of permanent congenital hypothyroidism) is the name given to a family of inborn errors of metabolism that lead to defects in the synthesis of thyroid hormone [1].

Thyroid dysfunction may be absent in life (adolescence or young adulthood) as goiter and minimal thyroid and growth abnormalities (cretinism). Milder defects will present later to neonatal or congenital hypothyroidism, goiter, mental retardation, depending on the severity of the inborn error. A severe defect will lead to inhibition of TSH secretion, deiodinase or thyroid hormone transport [4-7].

Macrosopically, the thyroid gland is enlarged (up to 600 g) and multinodular, and fibrous bands encapsulate individual nodules. Foci of thyroid cystic degeneration, thyroid hemorrhages or myxoid changes may be observed.

Histologically, the process is diffuse, without normal thyroid tissue. There is marked follicular hyperplasia, hypercellularity, with a predominance of solid and microfollicular patterns, sometimes papillary and insular formations, and decreased to absent colloid. The follicular cells typically exhibit severe cytologic atypia, including bizarre and markedly enlarged, hyperchromatic nuclear. Mitotic figures are presumably due to continuous thyrotropin stimulation. These nuclear changes are most common in the inter nodular areas rather than in the nodules themselves. The fibrosis entraps abnormal follicles, which can simulate a malignancy. Irregularities at the edge of the nodules can simulate capsular invasion [1,5,6,13]. The histology is thought to vary depending on site of enzymatic block [5,6,14].

Clinically the differential diagnosis for congenital hypothyroidism includes aplastic or hypoplastic thyroid and autoimmune thyroiditis. In this case, although autoimmune thyroiditis was suspected clinically, the lack of a lymphocytic infiltrate made autoimmune thyroiditis very unlikely [14].

Microscopically, features of DG are similar to those seen in iatrogenic goiters in infants following systemic administration of antithyroidal agents or radioactive iodine and those seen in Graves’ disease (thyroid diffuse hyperplasia). Dys hormonogenetic goiter can mimic follicular carcinoma or papillary carcinoma; In these cases, histologic criteria such as lack of capsular or vessel invasion and absence of cytoarchitectural features of papillary carcinoma raise the diagnosis. Thyroid undifferentiated carcinoma should be considered in differential diagnosis. This is due to the fact that the morphologic criteria employed to define undifferentiated thyroid carcinoma in most publications have been trabecular, solid, insular, cribriform growth patterns which can be seen in dys hormonogenetic goiters. But strict histologic criteria will help separate these lesions [1,5,6,14-17].

Follicular adenoma can occur in thyroid with DG and the capsule may appear focally violated by the hyperplastic process, in such case some observers have stated that diagnosis of malignancy can only be made if metastases have occurred [16].

Random nuclear atypia can occur in the form of enlarged pleomorphic nuclei with or without nuclear chromatin. These cellular changes can be mistaken for follicular, papillary, medullary, or undifferentiated thyroid carcinoma in cytologic specimens. Awareness of the clinical situation is, of course, extremely helpful [17].

Although rare, follicular carcinoma and papillary thyroid carcinoma or microcarcinoma have also been reported in patients with dys hormonogenetic goiters. There are two reports of metastatic thyroid carcinoma arising within a congenital goiter associated with a mutation in the TPO gene [3,8]. Despite the rare occurrence of thyroid carcinoma in dys hormonogenetic multinodular goiter, long-term follow-up and regular neck ultrasound imaging to prevent delayed diagnosis of thyroid carcinoma is recommended [8].

Without treatment patients die at birth. Treatment can be medical (thyroid hormone replacement) or surgical if there is symptomatic enlargement. Early treatment is particularly important in severe cases to avoid or diminish mental retardation and growth abnormalities. The prognosis is excellent with treatment [1,8-10]. Results after long-term follow-up have indicated satisfactory school performance, normal
mean IQ values, and minimal motor dysfunction in treated children. However, specific defects in hearing-speech performance scales and minimal central nervous system deficits have been described.

Conclusion

DG is a benign rare condition presenting architectural and cytological criteria that may lead to overdiagnosis of malignancy if not well known. So this entity must be recognized in lack of strict histological criteria of malignancy in patient with history of hypothyroidism since infancy. An exact molecular diagnosis allows genetic counseling and the identification of asymptomatic mutation carriers [9].
