Abstract

Neoplasms of the appendix are rare, accounting for less than 0.5% of all gastrointestinal malignancies and found incidentally in approximately 1% of appendectomy specimen. Carcinoids are the most common appendicular tumors, accounting for approximately 66%, with cystadenocarcinoma accounting for 20% and adenocarcinoma accounting for 10% [1]. We present a case of adenocarcinoma of appendix presenting only with a recurrent painless haematuria.

Case Report

A 79 year male presented to our surgical clinic with history of recurrent attacks of painless haematuria since last 5 months. There was no history of any fever, pain abdomen or any other urinary complaints. Patient had history of similar attacks 5 months back for which he was investigated by routine haemogram and urine analysis. During that time his total leucocyte count was around 9000 cu/mm with urine analysis showed 15-20 red blood cells without any pus cells. He was taken up for cystoscopy which revealed a congested area in the bladder mucosa suggestive of cystitis. Then oral and intravenous contrast enhanced CT scan abdomen was planned which was reported to be acute appendicitis complicated by cystitis. Conservative management in the form Oshner suprapubic cystostomy. Patient had an uneventful postoperative recovery then with repair of the urinary bladder wall was done under the cover of subsequent adjuvant chemotherapy.

Keywords: Adenocarcinoma; Appendix; Haematuria; Urinary bladder; Hemicolecotomy

Introduction

Neoplasms of the appendix are rare, accounting for less than 0.5% of all gastrointestinal malignancies and found incidentally in approximately 1% of appendectomy specimen. Carcinoids are the most common appendicular tumors, accounting for approximately 66%, with cystadenocarcinoma accounting for 20% and adenocarcinoma accounting for 10% [1]. Adenocarcinoma of appendix is most frequently perforating tumour of gastrointestinal tract due to anatomical peculiarity of appendix which has an extremely thin subserosal and peritoneal coat and the thinnest muscle layer of the whole gastrointestinal tract. In addition to the risk of perforation, mucinous adenocarcinoma of appendix have peculiar tendency for fistula formation. Many of unusual presentations reported for primary appendicular carcinoma are the results of fistula formation into the adjacent viscera such as the urinary bladder, bowel or vagina as well as extraperitoneally into retroperitoneal tissues or directly to the skin surface.

Many of unusual presentations reported for primary appendicular carcinoma are the results of fistula formation into the adjacent viscera such as the urinary bladder, bowel or vagina as well as extraperitoneally into retroperitoneal tissues or directly to the skin surface.
Discussion

A tumor of Appendix is a rare entity and was first reported by Berger in 1882. On review of literature only about 250 cases of appendicular adenocarcinoma have been reported since Berger first described it in 1882 [2]. Carcinoids are the most common appendicular tumors, accounting for approximately 66%, with cystadenocarcinoma accounting for 20% and adenocarcinoma accounting for 10%. Appendiceal adenocarcinomas fall into one of three separate histologic types. The most common mucinous type produces abundant mucin, the less common intestinal or colonic type closely mimics adenocarcinomas found in the colon, and the least common, signet ring cell adenocarcinoma, is quite virulent and associated with a poor prognosis [1,3]. Then there are the rare forms of cancers which include adenocarcinoid, non-Hodgkin's lymphoma, ganglioneuroma, and pheochromocytoma. Malignant tumour normally spreads intraperitonally through lymphatic. Hematogenous spread is rare. Benign primary processes are mainly mucinous epithelial neoplasms, also called adenomas, cystadenoma, and benign neoplastic mucocoele [3]. The majority of primary cancers of the appendix occur in 55-65 years of age, except for malignant carcinoid, which has a mean age of diagnosis of 38. Men and women seem to be at equal risk for all appendiceal neoplasms except for malignant carcinoid which may have woman to man ratio in excess of 3:1. Adenocarcinoma of the appendix is usually seen in the 6th to 7th decade with a male preponderance [2,4]. Appendicular adenocarcinoma usually presents as appendicitis with or without appendicular abscess, palpable abdominal mass, intestinal obstruction and pseudomyxoma peritonei [5]. Adenocarcinoma of appendix is most frequently perforating tumour of gastrointestinal tract due to anatomical peculiarity of appendix which has an extremely thin subserosal and peritoneal coat and the thinnest muscle layer of the whole gastrointestinal tract. In addition to the risk of perforation, mucinous adenocarcinoma of appendix have peculiar tendency for fistula formation [2]. Many of unusual presentations reported for primary appendicular carcinoma are the results of fistula formation into the adjacent viscera such as the urinary bladder, bowel or vagina as well as extraperitoneally into retroperitoneal tissues or directly to the skin surface. Extraperitoneal spread is associated with relatively good prognosis by preventing the development of peritoneal carcinomatosis [6,7]. Unusual presentation includes haematuria due to bladder infiltration, direct invasion of ascending colon detected on colonoscopy, intussusception, hydronephrosis due to ureteric infiltration, retroperitoneal abscess, vaginal bleeding, lower gastrointestinal bleed, epididimitis in case of metastases to the spermatic cord or testicles, ovarian mass due to Krukenberg tumor and cutaneous infiltration [5,8-14]. Management of appendiceal neoplasms should follow oncosurgical principles same as colorectal adenocarcinomas. If the patient presents electively, routine tumour markers including CEA, CT scanning and colonoscopy should be performed. Soft-tissue thickening and irregularity and thickening of the appendix wall and surrounding fat infiltration are nonspecific findings that suggest malignancy of appendix in CT scan abdomen. Gonzalez-Moreno and Sugarbaker found that those patients with mucinous type cancer had no survival benefit from hemicolectomy versus appendectomy.
They further mention that hemicolectomy is recommended in those patients where (1) it is necessary to clear the tumor or perform complete cytoreduction; (2) lymph node involvement is demonstrated by histopathological examination of the appendiceal or ileocolic lymph nodes; or (3) a nonmucinous subtype is identified by histopathological examination. In a study done by Pahlavan and Kanthanon adenocarcinoid tumors, he states that even though Goblet cell carcinoma is an aggressive tumor, a simple appendectomy is appropriate in most cases. However, he further states that a right hemicolectomy should be performed in the following scenarios: (1) cellular undifferentiation, (2) increased mitotic activity, (3) involvement of the base of the appendix, (4) lymph node metastasis, or (5) tumor size greater than 2 cm.

Surgical treatment of appendicular adenocarcinoma with right hemicolectomy has been reported as the treatment of choice because it facilitates lymph node resection to enable accurate tumour staging. Post-operative histopathological diagnosis after appendicectomy requires second surgery in form of right hemicolecotomy. Several studies have showed significantly better 5 year survival rates in patients treated with right Hemicolectomy compared to appendicectomy alone. In advanced disease, peritoneotomy and intraperitoneal chemotherapy should be considered. Once pseudomyxoma peritonei secondary to adenocarcinoma of appendix depends on the subtype and extent of disease. Mucinous adenocarcinoma is considered to have a more favorable prognosis [14-20].

**Conclusion**

Neoplasms of the appendix are rare, accounting for less than 0.5% of all gastrointestinal malignancies and found incidentally in approximately 1% of appendectomy specimen. Appendicular adenocarcinoma usually presents as appendicitis with or without appendicular abscess, palpable abdominal mass, intestinal obstruction and pseudomyxoma peritonei and is the most frequently perforating tumour of gastrointestinal tract due to anatomical peculiarity of appendix which has an extremely thin subserosal and peritoneal coat and the thinnest muscle layer of the whole gastrointestinal tract. Management of appendiceal neoplasms should follow oncological principles same as other colorectal adenocarcinomas. Adenocarcinoma of appendix should be kept in one of the rare differential diagnosis of any unexplained haematuria when all most common indications for the conditions are ruled out by investigations.
