A Single Stage Surgically Facilitated Rapid Orthodontic Technique with Alveolar Bone Augmentation in the Treatment of Various Dental Malocclusions: Case Series

Neetha J Shetty*
Department of Periodontology, Manipal College of Dental Sciences, Manipal University, India

Abstract

Background: Corticotomy when done on the bone over a root prominence can cause its demineralization, optimizing the response to applied orthodontic forces. This, when combined with augmentation of the alveolar bone can increase its volume and can also correct osseous dehiscences, and fenestrations over root surfaces. Here are cases that demonstrate the usefulness of periodontally accelerated orthodontic procedure in orthodontic treatment for the correction of various dental malocclusions.

Materials and methods: Orthodontic tooth movement combined with elevation of full-thickness flap, selective decortication, and ostectomy of alveolar bone, followed by bone grafting to accomplish the desired complete orthodontic treatment.

Results: The desired outcome of the PAOO as demonstrated by rapid tooth movement was observed in all the cases.

Conclusion: An efficient and stable orthodontic tooth movement can be achieved with the periododontally accelerated osteogenic orthodontics technique. With this technique, the teeth can be moved in one third to one fourth the time required for traditional orthodontics alone. Maintaining an adequate blood supply is an essential element in this technique as this is a physiologically based treatment consistent with a regional acceleratory phenomenon.

Keywords: Corticotomy; Orthodontics; PAOO; Periodontal regeneration

Introduction

Ideal aesthetic, restorative and reconstructive dental treatments are facilitated by favorably positioned teeth and an enhanced muco-gingival complex. Patients requiring comprehensive dental rehabilitation, correction of malocclusion or mutilated occlusion, frequently require orthodontic treatment in order to obtain a predictable, esthetic and functional treatment outcome. However, these patients have to undergo orthodontic treatment for 2-3 years which can be an obstacle in undergoing ideal rehabilitative dental care. By combining corticotomy with orthodontic treatment the time required for traditional orthodontic therapy is reduced by 60-75%. Here is a series of various orthodontic cases that have been treated successfully with satisfactory results within a short span of time using the PAOO technique.

Case Series

Presented below are cases that were treated in the Department of Periodontology, Manipal College of Dental Sciences, Manipal University, Mangalore. The cases were referred from the department of Orthodontics for periodontally accelerated tooth movement, as the desirable tooth movement was not achieved with the conventional orthodontic therapy over 2 years. All the 3 patients were systemically healthy and aged between 18 – 25 years.

Case-1 (bimaxillary protrusion)

Patient had a Class II skeletal base with proclined and forwardly placed maxilla and mandible. The molar relation was class II on both sides with a class I canine relation on both side and a spacing of 15 mm in lower arch and spacing of 1 mm in upper arch. Anterior mandible was Bolton’s excess of 1.6 mm. Ashley Howe’s analysis showeds that arch expansion was not possible and it was a boderline case. Arch Perimeter Analysis showed an excess of 12 mm. Lower midline was shifted to the left by 1 mm (Figures 1 and 2).

Case-2 (space closure)

Patient reported with proclined and forwardly placed maxilla and mandible and was diagnosed with dental class II relationship with spacing between all the anterior teeth. The patient was referred for PAOO for the closure of spaces (Figures 3 and 4).

Case-3 (intrusion)

Patient was diagnosed as having unilateral scissor bite on left side because of supra eruption of upper left posterior segment and lingual rolling in of lower left posterior segment. She was referred for PAOO procedure for intrusion of left posterior segment using temporary anchorage device i.e miniscrew implant and also uprighting of lower left posterior segment (Figures 5 and 6).

The procedure for all cases was as described below:

Flap design

A full thickness flap in the most coronal aspect of the flap with a split-thickness dissection performed in the apical portions. The

split-thickness dissection provides mobility of the flap so that it may be sutured with minimal tension. The flap is extended mesially and distally beyond the corticotomy areas to reduce the need for vertical releasing incisions. The initial incision is carried out on both surfaces of the alveolus (Figures 7 and 8).

**Decortication**

The purpose of the decortication is to initiate the RAP response and not to create movable bone segments. By use of No. 1 or No. 2 round burs in a high-speed handpiece, decortications are made in the alveolar bone. The corticotomies are placed on both the labial and lingual (palatal) aspects of the alveolar bone. Vertical grooves are placed in the interradicular space, midway between the root prominences in the alveolar bone. This groove extends from a point 2 to 3 mm apical to the crest of the bone to a point 2 mm beyond the apices of the roots. These vertical corticotomies are then connected with a circular-shaped corticotomy. Care is taken not to extend the cuts near any neurovascular structures. However, if this bone is estimated to be less than 1 to 2 mm in thickness, these perforations are omitted to ensure no damage to the radicular surface (Figure 9).

**Particulate grafting**

Grafting is done in the areas that have undergone corticotomies. The volume of the graft material used is dictated by the direction and amount of tooth movement to be achieved, the pretreatment thickness of the alveolar bone, and the need for labial support by the alveolar bone.

Decalcified freeze-dried bone allograft is placed on the area of corticotomy. The decorticated bone helps in retaining the graft material (Figure 10).

**Closure techniques**

Primary closure of the gingival flaps without excessive tension and graft containment are achieved with independent interrupted sutures (Figure 11). The type of sutures used is determined by the thickness of the tissue. The sutures that approximate the tissues at the midline are placed first to ensure the proper alignment of the papillae. The remaining inter-proximal sutures are placed next, followed by the closure of any vertical incisions. Periodontal dressing was given. The sutures were usually left in place for 1 week.

**Post-op patient management**

The choice of antibiotics and anti-inflammatory drugs to be prescribed depends on the clinician’s preference. Patient is asked to apply icepack on the affected area as it may decrease the severity of any possible postoperative swelling or edema. The patients were asked to return for postsurgical evaluation after 1-2 weeks for the first 2 months and mild orthodontic forces were applied, then monthly thereafter.

**Discussion**

Unlike usual corticotomy, PAOO cuts into the bone and decorticates it, thereby removing some of the bone’s external surface. The bone then goes through a phase of osteopenia, where its mineral content is temporarily reduced. Now, the tissues of the alveolar bone release rich deposits of calcium, and soon, new bone begins to mineralize in about 20 to 55 days. As the bone is still in a transient state with the bone being softer and less resistance to forces, braces can move the teeth very quickly. Studies have shown that the results of PAOO are as stable and long-lasting as conventional orthodontic braces [4-9].

Corticotomy facilitated orthodontics have been employed in various forms over the past to speed up orthodontic treatment. Kole [5-7] was the first to introduce this as a means for rapid tooth movement. Cortical plates of bone were believed to cause main resistance to tooth movement and by disrupting its continuity, orthodontics could be completed in much less time than normally expected. Kole’s procedure included the reflection of full thickness flaps to expose buccal and lingual alveolar bone, followed by interdental cuts through the cortical bone, barely penetrating the medullary bone. These vertical interdental cuts were joined by subapical horizontal cuts which followed osteotomy style, penetrating the full thickness of the
PAOO has expanded the realm of traditional orthodontic tooth movement (OTM) protocols. The spirit of interdisciplinary collaboration in orthodontics incorporates periodontal tissue engineering and regenerative surgery to expedite orthodontic tooth movement with reduced side-effects like root resorption, tooth devitalization, relapse, inadequate basal bone and bacterial time load factors like caries and infection [14]. This technique can be a “WIN-WIN situation” with an increasing number of adults considering orthodontic treatment.
