Abstract

Total thyroidectomy is not routinely performed for indications other than malignancy until the last quarter of the twentieth century. Despite significant advancement in surgical techniques of total thyroidectomy developed by Theodore Kocher and William Halsted, significant risks including damage to the recurrent laryngeal nerve, hematoma, and thyroid storm are still important considerations when weighing against surgical benefits. Currently, the use of neural integrity monitor (NIM) electromyogram (EMG) tracheal tube has become increasingly popular among surgeons to reduce risks of damage to the recurrent laryngeal nerves. The purpose of this case report is to discuss anesthetic management in a 48-year-old female patient undergoing total thyroidectomy using a NIM endotracheal tube (Medtronic Xomed, Jacksonville, Florida).

Keywords: Anesthesia; Hyperextension; Exubtation

Case Report

A 48-year-old female, 173 cm, 79 kg, was admitted for total thyroidectomy. The patient was diagnosed with benign multinodular goiter 2 months ago and had since elected to undergo total thyroidectomy. There was no underlying comorbidity defined during physical assessment. Airway assessment revealed Mallampati classification II, thyromental distance greater than 3 fingerbreadths, and full range of motion in the neck. Surgical history included ablation of the uterus. The patient had no reported drug allergies. Medications included multi-vitamin supplements. Base line vital signs were blood pressure (BP), 135/70 mmHg; pulse, 70/min; respirations, 17/min; SpO2 99%; and temperature 36.1°C. Preoperative laboratory values were all within normal defined range.

In preoperative holding unit, an 18-gauge intravenous (IV) catheter was inserted in the left hand; an infusion of 0.9% normal saline solutions was started. The patient reported nothing by mouth for 10 hours prior, and midazolam 2 mg IV was given prior to transferring to the operative room. Upon arriving to the operating room, the patient was then placed under volume control ventilation mode. Pre-induction vital signs were: BP, 132/79 mmHg; pulse, 82/min; respirations, 22/min; and SpO2 100%. Induction began with injection of diprivan 200 mg IV, fentanyl 100 μg IV, defasciculating dose of rocuronium 5 mg IV, succinylcholine 120 mg IV, and lidocaine 100 mg IV. The eyes were taped. A 7.0-mm NIM endotracheal tube (Medtronic Xomed, Jacksonville, Florida) was inserted in the trachea with the silver color-coded contact band appropriately placed between the vocal cords under direct laryngoscopy. End-tidal carbon dioxide (EtCO2) was detected, and bilateral chest breath sounds were present. The patient was then placed under volume control ventilation mode. Ventilator settings were: tidal volume, 600 mL; respirations, 10 breaths per minute; I:E ratio, 1:2; and PEEP at 5 cm H2O. Post induction vital signs were BP, 117/66 mmHg; pulse, 86/min; SpO2, 100%; and EtCO2, 34 mmHg.

General anesthesia was maintained under 1 L oxygen, 1 L of air, and 3% sevoflurane. An oroesophageal temperature probe was inserted. The patient was then repositioned in supine position with arms tucked in the neutral position on both sides. A soft shoulder roll was placed to maximize exposure of the neck. The head of the bed was elevated to 30°C. A lower body warming blanket was used. Eye protective goggles were placed to avoid accidental compression during the surgery. Dexamethasone 10 mg and fentanyl 100 μg IV were given immediately prior to incision. Continuous EMG was monitored throughout the case by technician at the bedside. The patient BP dropped to 79/54 five minutes after incision, phenylephrine 50 μg IV was administered. Blood pressure increased to 105/58.

Hemodynamics remained stable throughout the case. Fentanyl 25 μg IV was given after returning of spontaneous ventilations during. The function of recurrent laryngeal nerves was assessed using EMG prior to extubation. Endotracheal tube was removed after criteria for awake-extubation had been achieved. The patient was transferred and the immediate postoperative vital signs were BP, 153/75; pulse, 84/min; SpO2 100%, respirations, 13/min; temperature, 36.9°C. Discharge home instructions were generated.

Discussion

Subtotal thyroidectomy has been historically the preferred surgical intervention for management of benign thyroid disorders due to lower risks of inflicting permanent damage to the recurrent laryngeal nerve and causing hypothyroidism. However, subtotal thyroidectomy is associated with higher rates of recurrence (30% and 50%) compared to total thyroidectomy [1,2]. Moreover, there is always a chance for some nodules to be left behind following subtotal thyroidectomy [2]. With the introduction of NIM EMG tracheal tube (Medtronic Xomed) and hormone replacement therapy, total thyroidectomy has extended its indications for successful management of thyroid disorders other than malignancy. NIM-aided intraoperative dissection was able to successfully identify the external branch of superior laryngeal nerve (EBSLN) in 97.2% (95% confidence interval [CI], 95.5-98.9) of the cases compared to 87.5% (95%CI, 82.1-89.3) in traditional surgical
dissection alone [3]. The use of NIM EMG endotracheal tube is not without its risks. Malpositioning of endotracheal tube during induction and maintenance can inadvertently disrupt intraoperative neuromonitoring, resulting in increased risk of damage to the recurrent laryngeal nerves [4].

To optimize intubation condition, the patient should remain supine with head and neck in neutral position. Succinylcholine 1-1.5 mg/kg can be administered to facilitate intubation. No additional muscle relaxation is routinely required for remainder of the case [5]. The tube should be advanced between vocal cords with the exposed electrodes in contact of the patient’s vocal cords in order to generate an accurate electromyogram after the electrodes are connected to the multichannel EMG monitoring device [5]. Lidocaine 2% gel is not recommended as it can disrupt EMG readings. The patient should then be repositioned with the head elevated 30 degrees and the neck extended by placing a soft shoulder roll underneath [4]. Hyperextension of the patient’s neck should be avoided [4]. After the patient is repositioned, proper placement of endotracheal tube should again be verified using the EMG. The electric current should be set at 0.5 mA (the lowest recommended current to elicit EMG signals) initially and advanced to 0.8 mA until a continuous EMG can be generated [4]. The depth of endotracheal tube should be measured 20.6 ± 0.97 cm at lip in men, and 19.6 ± 1.0 cm at lip in women [4]. Eye lubrications and goggles are recommended due to limited visualization of the face after sterile drapes are applied [5].

Total thyroidectomy is performed using Kocher approach by making a transverse neck incision of 6-8 cm long [5]. Hemodynamic monitoring during the procedure is paramount; no additional muscle relaxation should be used. The use of ephedrine should be limited to persistent hypotension accompanied by bradycardia as it increases the release of catecholamines. The use of preoperative β-blockers is recommended for patients experiencing hyperthyroidism as they can effectively suppress adrenergic receptors [5]. In this particular case study, the patient did not take β-blockers because there was no evidence of hyperthyroidism identified.

Total thyroidectomy can also be performed under local/regional anesthesia via intravenous sedation accompanied by bilateral cervical blocks [6]. In preoperative area, local anesthetics are infiltrated through anterior rami of C2-C4 [6]. An ultrasound guided local anesthetic injection method is recommended. Transient paralysis to the recurrent laryngeal nerves can become an airway recovery when bilateral cervical blocks are placed [6]. After injection of cervical block on one side, it is important to assess the patient’s ability to phonate before proceeding to the contralateral side [6]. Local anesthesia is associated with superior patient outcomes compared to general anesthesia [6]. Some of the advantages including less bleeding, shorter hospital stay, lower incidence of postoperative nausea and vomiting, and reduced costs have been reported. Despite all the mentioned advantages, local/regional anesthesia for total thyroidectomy is still a less popular alternative among surgeons and patients in the United States.

The recommended extubation technique in patients undergoing total thyroidectomy is awake extubation. The ability of the patient to support his/her own ventilations and maintenance of a secured airway is paramount in managing anesthesia care for thyroid surgeries [2,4,5]. Excessive bucking and coughing should be avoided during recovery.

As it can lead to hematoma formation at the surgical site [5]. The use of a short acting opioid such as fentanyl or remifentanil has been reported to reduce coughing and bucking during recovery [7].
