Abstract

A 58-year-old male presented to the emergency department with right scrotal pain and swelling. The patient’s past medical history of epididymitis was unraveled. A multiplanar grayscale sonogram with Doppler scan of the scrotum and intra-testicular arterial pulse waveform was performed which demonstrated features of tubular ectasia of the rete testis. There was increased flow at the epididymal head which prompted the possibility of an inflammatory process consequently antibiotic therapy was administered. Tubular ectasia of the rete testis is a benign condition usually found incidentally, it has a prevalence of 1.64% in the population. This condition can be associated with a history of trauma, surgery, and inflammatory or infectious conditions. In case there is a suspicion of malignant etiology, magnetic resonance imaging (MRI) is used for better tissue differentiation.

Case Report

A 58-year-old male presented to the emergency department with right scrotal pain and swelling. The pain was severe, gradually progressive, radiated to the groin, and worsened with touch and movement. There was associated bilateral scrotal swelling and dysuria without fever, rash, or penile discharge. Our patient reported recurrent similar but less severe symptoms, as well as a history of epididymitis two years before presentation. A multiplanar grayscale ultrasound with color Doppler of the scrotum and intra-testicular arterial pulse wave was performed, which demonstrated normal homogenous echotexture bilaterally with no evidence of intra-testicular masses. Both testes demonstrated grossly symmetric color Doppler flow with normal intra-testicular arterial waveforms. A small anechoic left epididymal head cyst without evidence of a hydrocele was visualized (Figures 1 and 2). There were right and left tubular anechoic lesions located at the mediastinum testis, more prominent on the right, consistent with tubular ectasia of the rete testis. The right epididymal head demonstrated asymmetric increased color Doppler flow compared to the left, consistent with an inflammatory or infectious process. Subsequently, the patient was treated for infectious epididymitis.

Discussion and Conclusion

Tubular ectasia of the rete testis (TERT) is a benign condition found incidentally during testicular ultrasonography. Multiple small elliptically shaped anechoic lesions located peripherally, at the mediastinum of the testis, is demonstrated. It occurs due to the enlargement of the rete testis canaliculi. Clinically, these cystic changes are not palpable, but patients with this condition may present with scrotal swelling and enlargement especially with associated spermatoceles. Additionally, they show no signs of blood flow on Doppler scan. TERT is bilateral in almost one-third of all cases and most have associated epididymal pathologies such as epididymitis and epididymal cysts [1-6].

The prevalence of cystic transformation of the rete testis to tubular ectasia was found to be 1.64% (n=38) in a study by Nistal et al. [6]. This study included testicular and epididymal specimens acquired from 2316 men, the majority from autopsies (n=1,798) and the rest from surgery (n=518). Testicular cysts which include a wide range of differentials, one of which is TERT, has a prevalence of 10% according to Gooding et al. [7].

The flow of sperm starts at the seminiferous tubules which join to form lobules. Each lobule encompasses several hundred seminiferous tubules which assemble to form the straight tubules. The straight tubules converge together forming the rete testis. From the rete testis, efferent ductules extend and merge to form the head of the epididymis. The epididymis has a head, body, and tail through which the sperm travel toward the vas deferens and onward to the external genital tract (Figure 3) [3].

Obstruction or stenosis within the previously described tubular pathway could potentially lead to the development of tubular ectasia of the rete testis. The cystic transformation of rete testis is speculated to take place due to the consequent back pressure following obstruction or stenosis. The most common locations for obstruction includes the efferent ducts, testis epididymis junction, and within the epididymis [4,6]. The major underlying causes of obstruction or stenosis leading to TERT, are classified into mechanical compression of extratesticular space characterized by branching patterns, which are peripherally located within the mediastinum testis. These cystic lesions have no solid component and clinically are not palpable. They usually present at a median age of 62. The classic associated features of this condition help avoid unnecessary procedures and surgeries. On the other hand,

features suspicious for malignant lesions such as palpable testicular masses, cystic lesions associated with a solid mass, and presentation at a younger age, prompt further workup [2-5]. Magnetic resonance imaging is used when in doubt, due to its precise tissue differentiation, which helps in confirming or excluding other differentials [1]. On T1 and proton-density-weighted images, tubular ectasia of the rete testis

Figure 1: (A) Longitudinal grayscale ultrasound view of the right testis, demonstrated multiple anechoic lesions at the middle mediastinum of the testis with (B) color Doppler demonstrating the lack of blood flow within this lesion. (C) Longitudinal grayscale ultrasound view of the left testis demonstrating multiple small anechoic lesions with a branching pattern, and (D) color Doppler scan showing the lack of blood flow within the lesion.

Figure 2: (A) Bilateral transverse grayscale ultrasound view of the right and left testis demonstrating multiple small anechoic lesions bilaterally, and (B) color Doppler showing the lack of blood flow within the anechoic lesions.
demonstrates homogenous signal intensity lower than that of the testis. On T2-weighted images, it could be indistinguishable from the testis. Following IV gadolinium administration, ductal ectasia of the rete testis normally does not enhance (Table 1) [5].

The differential diagnosis of TERT includes benign and malignant conditions. Benign conditions include cystic dysplasia, testicular epidermoid cysts, simple testicular cysts, tunica albuginea cysts, and intra-testicular varicoceles. Malignant conditions which mimic TERT on imaging mainly include mature cystic teratomas, papillary adenocarcinomas of the rete testis, and metastatic tumors within the ducts of the epididymis (Table 2) [1,8-15].

In conclusion tubular ectasia of the rete testis is a benign condition easily identifiable using ultrasonography which demonstrates its characteristic benign cystic features. This avoids unnecessary invasive procedures. For management, no treatment is required (Table 1) [6].

procedures and/or surgical interventions. When in doubt, magnetic resonance imaging is used for further evaluation.

Conflict of Interest

As per our local Institutional Review Board (“IRB”) guidelines there are no restrictions to publish case reports as long as patient information are kept confidential. Therefore, since there are no identifiers to patient’s identity our case report falls within the confines of appropriate ethical conduct.
