Abstract

Helium-neon (He-Ne) laser has been used in many clinical fields, and caught our interest in cancer treatment. We conducted the study of He-Ne laser in lung cancer for the sake of the most common cause of cancer deaths worldwide, and up to 50% of the patients with advanced non-small-cell lung cancers with brain metastases. In this study, we used two human lung cancer cell lines A549, H1299, bronchial epithelial cell line BEAS-2B to detect the effects of He-Ne laser on proliferation and migration capabilities by MTT, trypan blue exclusion and wound healing analysis, followed by Western blot analysis to identify the putative signaling pathway evoked by the He-Ne laser. Low-power He-Ne laser slowed H1299 migration by inhibiting Extracellular signal-regulated protein kinases (ERK) phosphorylation, and decreased A549 cell proliferation via p38 up-regulation. However, He-Ne laser increased NT2 cell proliferation and migration activities through ERK activation. The low-power He-Ne laser had diverse effects on different cells, possibly suppressive effect on malignant cells, but growth provocation on pluripotent cells. We proposed that the low-power He-Ne laser renders a beneficial alternative for cancer treatment and for tissue repair.

Keywords: NSCLC; He-Ne laser; Proliferation; Migration; MAPK

Abbreviations:

ERK: Extracellular Signal-regulated Protein Kinases; JNKs: Jun N-terminal kinases; MAPK: Mitogen-Activated Protein Kinases; PDT: Photodynamic Therapy

Introduction

Lung cancer is the most common cause of cancer deaths in the world, accounting for 27.19% of all cancer deaths in the United State of America [1], and in Taiwan the crude death rate gradually increased during the past decade from 2004 to 2013 [2]. No matter by chemotherapy and radiotherapy, unsatisfactory outcomes in lung cancer patients are often attributed to the difficulties for early detection and sometimes to limited interventional feasibility to target the tumour bulk.

In this study we explored the alternative approach for the management of lung cancer. Photodynamic therapy (PDT) has been proposed as a treatment option for the centrally-located early lung cancer at stage 0 (TisN0M0) and stage I (T1N0M0) [3], including the lung cancers. Thus, we would like to investigate the effects of the He-Ne laser irradiation in lung cancer cells and to evaluate its application in lung cancer treatment.

Cell culture

Human lung adenocarcinoma cell lines A549 (ATCC\® access number, CCL-185TM), H1299 (ATCC\® CRL-5803TM), malignant...
pluripotent human testicular embryonal carcinoma cell NT2 (NTERA-2 clD1, ATCC® CRL-1973TM), and the primary immortalized bronchial epithelial cells, BEAS2B (ATCC® CRL-9609TM) were all maintained at 37°C in a humidified atmosphere containing 5% CO₂. Cells were cultured in DMEM or RPMI 1640 medium (Life Technologies, Rockville, MD, USA) supplemented with 10% heat-inactivated fetal bovine serum (FBS; Life Technologies) and 1% penicillin-streptomycin (Life Technologies).

Low-power He-Ne laser irradiation

The experiments were conducted with a low-power He-Ne laser (Model JY-ILIB-5, Bio-Resonancehuman energy Corp, Taipei, Taiwan), which emits 632.8 nm wavelength with an output of 4.0 mW for 0, 5, 10, 15 and 30 minutes. Dose effect was determined by the treating durations. The cultured cells were harvested from the culture Petri dishes for 24 hr incubation initially, and then rinsed once by phosphate-buffered saline (PBS) before irradiation with 1ml retained in the microtubes. The electrode tip of He-Ne laser was gently agitated below the PBS surface with emitted laser to contact cells directly. Throughout each experiment all dishes (including controls) were maintained in PBS at room temperature. All irradiation experiments were at least repeated in triplicates.

Cell viability assay

The cells were seeded onto 96-well plates at 4,000 cells per well in culture media (100 μl). After culturing for various durations, cell numbers were measured by thiazolyl blue tetrazolium bromide (synonym as methylthiazolyldiphenyl-tetrazolium bromide, MTT) assay according to the protocol (Sigma-Aldrich Corp., St. Louis, MO, USA). In briefly, 10 μl of the MTT solution (5 mg/ml) were added to each well and the cells were cultured for another 4 hr at 37°C. One hundred microliters of 0.04 N HCl in isopropanol were then added to each well, and mixed vigorously to solubilize colored crystals produced within the cells. The absorbance value at 570 nm was measured by a multi-well scanning spectrophotometer.

Growth curve determination

The effect of He-Ne laser irradiation on cellular proliferation was assessed by visually counting the number of cells in conjunction with trypan blue exclusion. Cells were seeded with a density of 1-4×10⁵ cells/well and were incubated overnight. Then cells were irradiated with 4.0 mW He-Ne laser radiation for various time courses and incubated for 1–3 days. The cells were then washed with PBS and trypsinized, followed by mixing with equal volume of trypan blue dye. Finally, the number of living cells was counted with a hemocytometer chamber.

Cell migration assay

The cells were seeded into 6 cm culture dishes at a density of 2.5×10⁵ cells and cultured in medium containing 10% FBS for 24 hr. Then the nearly confluent cell monolayer was carefully scratched using a 10 μl pipette tip. Any cellular debris was removed by washing with PBS. After making wounds, the cultures were incubated at 37°C and we took pictures immediately (t=0), 4, 8 and 12 hrs later. The number of cells migrating into the cell-free zone was counted under a light microscope. The experiments were performed in triplicate.

Western blot analysis

Western blot analysis was used to examine the expression levels of the affected protein after low-power He-Ne laser irradiation in various cell lines. The details of these procedures were described previously [23]. The specific primary antibodies for anti-phospho-ERK1/2 (T202/Y204, #9101, Cell Signaling Technology), anti-total ERK2 (#9102), and anti-total p38 MAPK (mitogen-activated protein kinases) (#9212), all from Cell Signaling Technology, were applied for the serial investigations, with α-tubulin used as an internal control.

After incubation with the primary antibodies, membranes were washed three times with TBST (Tris-buffered saline and Tween 20) solution, followed by incubation with horseradish peroxidase (HRP)-conjugated secondary antibodies (Santa Cruz Biotechnology, Santa Cruz, CA, USA) and detection using an enhanced chemiluminescence detection system (ECL, GE Healthcare, Piscataway, NJ, USA).

Statistical analysis

All experiments were performed in triplicate and analyzed by ANOVA (Excel, Microsoft). All statistical tests were two-sided, and P value <0.05 was considered statistically significant. Where appropriate, the data are presented as the mean ± standard deviation.

Ethical declaration

This is a cell-based study, without laser use for the animals and humans. Thus our work did not have the revisions by the Institutional Animal Care and Use Committee (IACUC) and Institutional Review Board (IRB).

Results

Low-power He-Ne laser irradiation significantly slowed A549 cell proliferation

At first we would like to explore the effect of the low-power He-Ne laser on the cell growth by the proliferation and viability assays. The primary immortalized bronchial epithelial cell, BEAS2B, and lung cancer cells, A549 and H1299 cells, were applied to assess the effects of He-Ne laser irradiation on cell growth by trypan blue exclusion assay (Figure 1).

The low-power He-Ne laser irradiation lacked the effect on BEAS2B cells (Figure 1A). However, no matter long- (30 min) or short-treating (5 min) duration of the laser exposure applied with 4 mW He-Ne laser irradiation, the cell numbers of A549 cells decreased significantly after 48 hr, as compared with the ones without treatment (0 min, P<0.05; Figure 1B).

For the study of H1299 cells, there was no significant change of the cell numbers after low-power He-Ne laser exposures (Figure 1C). On MTT assay for the cell viabilities of these cell lines after laser emission, as shown in Figure 2A and 2C, long exposure time (30 min) of low-power He-Ne laser irradiation could lead to a decrease in cell viability of both BEAS2B and H1299 cells, but not for the cells on the shorter time treatment.

In contrast, both short and long exposure of low-power He-Ne laser irradiation resulted in decreasing cell viabilities after 2 days in A549 cells (Figure 2B, P<0.05). This result was consistent with the trypan blue exclusion data.
Low-power He-Ne laser irradiation significantly suppressed H1299 cell mobility

Besides cell proliferation and viability, we investigated cell mobility analyzed by the scratch wound healing assay (Figure 3), which implies the reactions between tumor cells and extracellular matrix while invasion. The low-power He-Ne laser irradiation had no effects on A549 cell mobility (Figure 3A). But lower migration capability of H1299 cells occurred after low-power He-Ne laser irradiation with longer treatment time, more prominent after harvesting for 8 and 12 hrs as compared with that of the untreated control group (Figure 3B, P<0.05). Although less viability changes on laser treatment in above experiment, H1299 cells had more suppression of cell mobility after long-duration laser irradiation.

Low-power He-Ne laser irradiation increased p38 expression levels in A549 cells and decreased the phosphorylation of ERK in H1299 cells

As already known, mitogen-activated protein kinases (MAPKs) play critical roles in cell proliferation, migration, oncogenesis, differentiation, inflammation and stress responses [24,25]. Therefore we further investigated the intracellular signaling molecules for the behavioral changes of the A549 and H1299 cells. Laser-irradiated cells followed by harvest for 48 hr were then subjected to Western blot assay.

In A549 cells, the expression levels of p38 significantly increased 2.5 to 5.4 folds after low-power He-Ne laser irradiation (Figure 4A). In H1299 cells, the longer exposure (durations, 15 and 30 min) on low-power He-Ne laser irradiation decreased the phosphorylated ERK, but no significant changes in the expression levels of p38 (Figure 4B).
These results may suggest different molecular mechanisms after low-power He-Ne laser irradiation in these two lung cancer cells.

Discussion

Low-power laser irradiation has been applied in wound healing, adjuvant treatment of spinal cord injury, and mucositis caused by cancer therapies [13,26]. But this study stated the direct effects on lung cancer cells by low-power He-Ne laser irradiation. Low-power He-Ne laser irradiation significantly decreased proliferation of A549 cells by increasing expression level of p38 protein. In addition, it also suppressed H1299 cell migration capability via lowering phosphorylation of ERK. To our knowledge, this is the first study to demonstrate that the low-power He-Ne laser irradiation could suppress cell proliferation and migration through the MAPK alterations in lung cancers.

However, the low-power He-Ne laser irradiation on the pluripotent NT2 cells had the contrary results. It increased NT-2 cell proliferation and migration via ERK activation. Low-power laser irradiations have been demonstrated to promote proliferation in several fairly-differentiated cell types, including endothelial cells, lymphocytes, fibroblasts, melanocytes, and HeLa cells [19,27–31]. Mechanisms for the mitogenic effects of low-power laser irradiation have been stated, including MAPK pathway [32]. It has been proposed that laser induced dimerization of some ligand-free receptors, and then autophosphorylation resulting in the downstream effects [9] such as the increased concentration of intracellular calcium and activated calcium channels [33,34]. Moreover, it has been shown that low-power laser energy would result in increase in reactive oxygen species, adenosine triphosphate or cyclic AMP via energy absorbed by mitochondrial respiratory chain components [35,36].

In mammalian cells, there are at least three MAPK cascades that are activated by different environmental stresses. For example, p38 and the Jun N-terminal kinases (JNKs) are strongly activated by stress signals such as high osmolality, pro-inflammatory cytokines, heat shock, and UV irradiation [37,38]. The ERK was vital in growth factor-induced mitogenesis, cell transformation, and differentiation [39]. A known result stated that low-power He-Ne laser irradiation provoked proliferation of melanoma cells through the mitochondrial pathway, which subsequently activates JNK and increases the transcriptional activity of activator protein-1, AP-1 [40]. In skeletal muscle cell regeneration, low-power He-Ne laser irradiation could activate ERK but with no effect on JNK or p38 [41].

As a comparison in the present study, the low-power laser irradiation promoted NT2 cell proliferation with ERK activation. Interestingly, low-power laser irradiation had no effect on H1299 cell or even decreased A549 cell proliferation through up-regulation of p38 protein kinase in this study. The negative p38 signaling effect on cell proliferation and the underlying molecular mechanisms had been documented [42]. Some studies indicated that p38 could mediate either DNA-damage-induced apoptosis or oncogene-induced senescence through activating p53, a downstream effector of p38 [43,44]. Therefore, p38/p53 axis would be supposed to conduct the proliferation inhibition of A549 cells, which contain wild typed p53, after low-power He-Ne laser exposure. However, p53-null H1299 cell line lost this effect on cell proliferation. The role of p53 on lung cancer cells after laser treatment needs more work to dissect.

Besides the cell proliferation, differentiation, inflammation, oncogenesis, and stress response, there was also evidence about MAPK family contributing to cell migration [24]. On using the specific inhibitors for the ERK pathway, migration of different cell types in response to growth factors, cell matrix proteins, and other stimuli
became inhibited [25]. Our results showed that low-power laser irradiation could suppress H1299 cell migration abilities via inhibiting ERK activation. In contrast, the NT2 cell told a different story about the enhanced cell migration through increase in ERK phosphorylation. Direct activation of the downstream signaling substrates or indirect responses via other signal pathways activated after low-power laser irradiation still needs to be identified. For clinical interest, migration changes after low-power He-Ne laser irradiation may be a critical issue for dealing with metastasis of human lung cancers. For instance, it has been demonstrated that the combination of vascular endothelial growth factor inhibitors could improve the therapeutic efficacy of PDT [45]. Therefore, the combination of PDT using low-power He-Ne laser irradiation and molecule-targeted agents may become new clinical strategies or treatment options for patients with lung cancers.

Some limitations existed in our study. First, in this cell-based study the treatment device of the laser application was not the clinical investigating route. Laser energy may activate the blood cells or degrade the molecules in blood streams resulting in various cell responses, and in a more diverse way from our cell model. Second, the heat production caused by the laser may be a puzzling issue on conducting our bench study, especially while the longer irradiating duration. We monitored the temperature of the laminar hood but not the one of the culture dishes during the laser treatment. Third, we did not test other cancer cell lines of different tissue origins, or the application of the pharmacological inhibitors for the signal pathways in this study. It was mainly attributed to the limited financial support. Fourth, we did not administrate the chemotherapeutic agents concurrently with the laser treatment in this study for the possible synergic or additive effects. Although someone may wonder the palliative role of low-level He-Ne laser in cancer treatment, it is worthy to conduct the clinical application of the laser on chemotherapy for patients with lung cancers.

In conclusion, we stated that the low-power He-Ne laser irradiation inhibits lung cancer A549 cell proliferation and suppresses H1299 cell migration through p38 protein up-regulation and ERK phosphorylation reduction, respectively. He-Ne laser may induce different effects on lung cancer cells with diverse genetic background. In addition, the low-power He-Ne laser irradiation promotes proliferation and migration capabilities of human NT2 cells through ERK activation. All these results suggest that the low-power He-Ne laser irradiation may have various effects on cancers, possibly related to the cell types. Catheter-assisted laser transmission may emerge the one of the culture dishes during the laser treatment. Third, we did not administrate the chemotherapeutic agents for dealing with metastasis of human lung cancers. For instance, it has been demonstrated that the combination of vascular endothelial growth factor inhibitors could improve the therapeutic efficacy of PDT. Therefore, the combination of PDT using low-power He-Ne laser irradiation and molecule-targeted agents may become new clinical strategies or treatment options for patients with lung cancers.

Acknowledgments

This work was supported by the grant from the Cardinal Tien Hospital, Taipei, Taiwan (700192) and in part by the grants from the National Science Council (NSC), Taiwan (NSC99-2628-B-030-002-MY3, NSC101-2313-B-030-005). We also thank the Bio-Resonance human energy Ltd Corp for providing the instrument of the low-power He-Ne laser for this study.
