Abstract

Probiotics are live microorganisms which when administered in adequate amount confer a health benefit on the host. Beneficial aspects of probiotics include alleviation of lactose intolerance, control of diarrhoea, urogenital-infection, reduction in cholesterol level and relief from irritable bowel syndrome, antioxidant potential, and pathogen inhibition. These days research is focussing on probiotics usage in colon cancer prevention because of its positive outcomes. Scientific evidences indicate a strong association between diet, lifestyle, and changes in gut microflora composition which may initiate the onset of colon cancer. Probiotic usage in colon cancer prevention is a new direction of research and most of the studies related to colon cancer prevention are still unclear and effects are in observed form, so confirmation studies are needed in this respective area and also there is a need to standardize methodology. This review presents information about mechanism of different probiotic actions, factors contributing colon cancer risks and how probiotics are helpful in preventing colon cancer with supporting scientific based evidence and various experimental studies.

Keywords: Probiotics; Colon cancer; Colon cancer risk; Cancer prevention

Introduction

Trillions of bacteria inhabit human body and these organisms distributed at specific sites, form complex communities on the skin, mucosal surfaces, but the largest group is found in the colon (10^13 microorganisms g^{-1} gut content). Colonic resident micro flora contributes to about 95% of the cells within the body making the colon a very metabolically active organ. Scientific evidence support that the eukaryotic host has co-evolved with their symbiont in a mutualistic relationship for their nutritional benefits from each partner. Microbes in the gut exert a significant effect on host biochemistry such as oxidation-reduction potential of luminal contents, enzymatic activity of intestinal contents, host physiology, short chain fatty acid production in the lumen, host immunology and modification of host-synthesized molecules [1-5]. There is an established association between existing microbiota and intestinal function for maintaining of homeostasis, building of balanced immunity. Any microbial alterations may lead to increased chances of the disease by mean of immune function disturbances [6]. Genetic and environmental factors also disrupt the symbiotic interaction by altering the microbial composition, distribution and the metabolic activity which may result in dysbiosis, a contributing factor for the onset and progression of several chronic diseases including cancer. Interindividual variations of microbiota of host are associated with each host genetics and environmental factors like diet, physical activity, stress, smoking, drugs, illness, and antibiotics [7-10]. However these organisms interact with the host at multiple levels to maintain its normal functions. Disruptions in this complex ecosystem crosstalk result in physiological changes associated with colorectal (colon+rectum) tumour genesis as well as cell proliferation, programmed cell death process and immune responses [11]. Evidences have showed that modulation of the host gut microbial environment by using probiotics, (Microbial cell preparations or components of microbial cells) through ingestion or administration is a protective approach for proper maintaining of healthy gut micro-biota and also reduce the development of colon cancer risk [11-14]. In 400 BC, Hippocrates mentioned the role of the human gut in disease through statement‘death sits in the bowel’ [15]. Again after approximately 2000 years later, Elie Metchnikoff, by observing longevity in Bulgarian peasants, extolled the virtues of consuming fermented dairy products. In 1907, he established scientific basis for the health benefit of lactic acid bacteria in his book “The Prolongation of life” printed in 1907. He declared that some of the bacterial organisms present within the bowel served as a source of ‘toxicants’, harmful substances that contributed to sickness and aging. He also suggested that “Intestinal microbial dependence on the food makes it attainable to adopt measures to modify the flora in our bodies and to exchange the harmful microbes by beneficial microbes”. Lactic acid fermented foods together with other cultured dairy products became the part of human diet for thousands of years and considered to have beneficial effects [16-17]. Probiotic term has undergone number of variations in its definitions; the present accepted definition for probiotic is given by Joint FAO/WHO working group 2002 [12] and it is the most accepted one. According to it probiotics are defined as “Live micro-organism which when administered in adequate amount confer a health benefit on the host ”.

Recently at International Scientific Association for Probiotics and Prebiotics (ISAPP) [18] consensus meeting on the scope and appropriate use of the probiotic term definition was worded with grammatical correction. According to it probiotics are “Live micro-organism that, when administered in adequate amounts, confer a health benefit on the host “.

Delivery of probiotics is considered an important issue. Though it can be delivered in form of capsules, tablets; generally a food product is considered best delivery vehicle for a probiotic microorganism to reach the GI tract of the human body in a live and active form. Upon consumption of probiotics in a range of $10^6$ to $10^{11}$ cfu/day could be able to reduce the incidence as well as severity of some illnesses that associated with the intestine [19]. Probiotics like *Lactobacilli* and *Bifidobacteria* are considered as most successful probiotics having a long history of safe usage. In addition to this, these probiotics fall in the category of Generally Recognized as Safe (GRAS) because they are able to stay in the human body without causing harm [20]. Organisms from different genera like *Lactobacilli*, *Bifidobacterium*, *Pedicoccus Leuconostoc*, *Enterococcus* and yeast such as *Saccharomyces boulardii* are recognised as probiotics [21]. Beneficial effects of probiotics include alleviation of lactose intolerance [22], inhibition of intestinal pathogens [23], control of diarrhoea [24]. Other effects studied include reduction in cholesterol level [25], urogenital infections [26], relief of irritable bowel syndrome [27], improving mineral absorption [28], enhanced immune response [29], and anti-mutagenic and anti-carcinogenic activity [30]. The aim of this paper is to present information about risk factors of colon carcinogenesis, mechanism of different probiotic actions and how probiotics are helpful in preventing colon cancer with their supporting scientific based evidence and various experimental studies etc.

Factors Contributing Colon Cancer Risk: Response

Cancer has become a globe public health problem. Worldwide colon cancer strikes more than 1 million people annually and is responsible for death of more than 500,000 person [31]. According to World Health Organization (WHO), by 2030 there will be about 17 million deaths, 27 million new cases of cancer and 75 million people living with the disease. When compared to the other types of cancers, colon cancer is found to be the most common death cause [32,33]. Various factors that may increase colon cancer risks includes (Figure 1 and 2):

![Figure 1: Mechanism of different probiotic action](image-url)
Diet

Various studies show that diet contributes to 20%-42% in causing human cancers and for colon cancer it is about 50%-90% [34]. The very fact that 90%-95% cancers are due to lifestyle factors, environmental toxins, and infections and the rest 5% to 10% are due to genetics these factors provide a major chance for the prevention of colon carcinoma [35]. Pyrolysis products of cooked food can also initiate colon cancer [36]. Diets low in whole grain, vitamin D, fruits, vegetables, calcium, fibre and omega-3 fatty acids, and diet rich in red and processed meats, refined starches, sugar, and saturated and trans-fatty acids are closely related to an increased risk for colon cancer [37,38]. Interestingly intake of high fat favours the formation of bile acids (BA) into the duodenum and then activates bacterial 7-alpha-dehydroxylase to convert it into secondary bile acids. In several animal model studies it was observed that these bile acids, deoxycholic acid and lithocholic acids are able to promote colon carcinogenesis. Experimental studies also reported that addition of cholic acid to the rats diet, increased proliferation in colonic epithelial cells was observed [39,40]. Hence it has been hypothesized that there is a association between the diet and colon cancer, as diet has influence on composition and metabolism, creating relevant factors as a base of the disease [41].

Aging

Aging is additionally one of the factor connected with an increased risk of colon cancer [42]. Evidences exploring the results of aging on the faecal microflora have revealed that over 70 years there is a decrease in the count of Bifidobacteria and Lactobacillus and increases in clostridia occur [43,44]. The modifications that occur among microflora are thought about the result of dietary and activity changes as a results of age [45,46]. These bacteriological changes have been reported to often coincide with an rise in gastroenterological infections [47] and gut cancers.

Genomic instability

Colon cancer development is a multistage process and it involves accumulation of mutations in certain tumour suppressor genes and proto-oncogenes leading to cancer initiation [48]. The fundamental process associated is genomic instability and is related to the gene rearrangement or loss of DNA fragments, aneuploidy and loss of heterozygosis [49]. In addition, inactivation of tumor suppressor genes like APC, DCC, DPC4 and p53, along with the activation of oncogenes, of which the family of RAS genes play an important role in the malignancy appearance [50]. Adenomatous Polyposis Coli (APC) is considered as a tumor suppressor protein and it acts as an antagonist to the Wnt signalling pathway. Usually this pathway plays a key role in elevating colonocyte proliferation and suppressing caspase mediated cell death process in both humans and rodent models of experimentally induced colon carcinoma. Any gene defects in APC will usually cause an autosomal dominant premalignant disease called as Familial Adenomatous Polyposis (FAP). It is usually involved in growth to malignancy and inhibits programmed cell death process in colonocytes and thereby causes the initiation of the colon carcinogenesis [51-53].

Obesity

Now-a-day obesity has been established as a colon cancer risk factor [54]. Evidence shows that there is a strong relation between increased body mass index (BMI) and deaths related to the cancer. It is found that almost 14% of cancer death in men and 16-20% of cancer deaths in women were found to be due to obesity [55]. In humans, body mass index is somehow proportional to the leptin levels and are raised in obese individuals. Leptin is the product of the ob (obese) gene, play a key role in energy expenditure. Since obesity is known to increase the risk of certain cancers, much effort has been directed at elucidating the possible role of leptin in cancer development [56-59]. However there is very less evidence for involvement of leptin in colon cancer in a clear-cut manner [60]. Leptin was shown to work as a mitogen for intestinal...
epithelial cells and furthermore decreased apoptotic cell death in a cancer cell line [61]. It has been shown to induce invasion of collagen gel by cell lines derived from colonic adenomas [62]. Furthermore leptin was also shown to extend the growth and proliferation of a colon cancer cell line, as proof by BrdU incorporation and c-fos expression [63].

**Diabetes**

Currently investigations are going on the link between gut and type 2 diabetes. Animal based models have established a relation between altered microbial composition to the development of diabetes, obesity and insulin resistance in the host system by several mechanisms like altered fatty acid metabolism, harvesting more energy from the diet and adipose tissue and liver composition, modulation of gut peptide PYY and glucagon-like peptide (GLP-1) secretion, lipo-polysaccharide toll-like receptor-4 axis activation and increased inflammation [64]. In some studies they showed that obesity is the strongest independent determinants of insulin resistance and hyperinsulinaemia [65-68]. As the blood insulin levels increases, the levels of insulin-like growth factor binding protein-1 get decreases and it leading to increased levels of free insulin-like growth factor 1 (IGF-1). IGF-1 acts as a pro-carcinogen, each by decreasing cell death and promoting cell growth [69,70] IGF-1 is understood to be involved in the development, progression, and colon cancer metastasis [71,72].

**Atherosclerosis and colon cancer link**

Latest research in obesity noted that adipose tissue is considered as an active endocrine organ and they produce different kinds of the bioactive molecules characterized as adipokines [73,74]. It is well evident that as the obesity (adiposity) level increases, there is impairment in the levels of anti-inflammatory/adipokines expression, especially adiponectin (Adiponectin is a peptide with 244 amino-acids, secreted from adipose tissue) thereby it lead to an increased levels of pro-inflammatory as well as atherogenic adipokines. These discussed pro-inflammatory/atherogenic adipokines include Resistin, tumor necrosis factor (TNF-α), Interleukin-6, Macrophage Chemoattractant Protein (MCP) -1 etc. Therefore the aforementioned adipokines can able to contribute the initiation and progression of atherosclerosis in a number of ways, such as regulating the endothelial cell function (which is to be considered as an initial onset event in atherosclerosis), vascular inflammation and formation of plaques [75,76]. In addition, in another study it is noted that hypoadiponectinemia is closely concerned with inflammatory atherosclerosis signifying that to maintain the usual vascular wall in non-inflammatory state sufficient levels of adiponectin is needed [77]. Low levels of adiponectin also play a role in causing obesity linked malignancies risks which include endometrial, prostate, breast and more specifically colon cancer [78]. Evidences based studies supporting that adiponectin can inhibit colon and rectum cancer through the activation of adenosine monophosphate-activated protein kinase followed by mammalian target of rapamycin (mTOR) pathway. Any deficiency in adiponectin can contribute inflammation induced colon cancer [79,80].

**Gut microbiota contribution**

Intestine is composed of over 1000 different bacterial species and the microbial population is heterogeneous in nature. The microbial density within large intestine is 12-fold beyond that in the small intestine. So there is an estimated 12-fold increase in cancer risk in the large intestine compared with the small intestine [81]. It has been revealed that microflora resident in colonic region are able to convert harmless compounds into metabolites that causes inflammation or tumourigenesis [82]. The microflora in intestinal region can contribute to carcinogenesis by producing enzymes like β-glucosidase, β-glucuronidase,nitroreductase and azoreductase [83]. The most common pathogens associated with the production of β-glucuronidase are E.coli and Clostridium perfringens [84]. These faecal enzymes may hydrolyse glucuronide, a compound that is needed to detoxify foreign compounds and produces cancer causing aglycones in intestinal lumen [85].

**Role of Probiotics in Colon Cancer Prevention**

Research has been conducted to explore the role of probiotics in colon cancer prevention. How gut microbiota influence the development of colon cancer, specifically how the gut micro biome contributes colon cancer through initiation of inflammation [94,95]. Researchers suggested that the prevention of colon cancer might occur through intervention of symbiotics (probiotic+prebiotic) that allow certain substantial changes in the gut micro biota [96]. According to Roberfroid [97] prebiotics are defined as “These are the non-digestible food ingredient that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon, and thus improves host health.”

But recent and well accepted definition for prebiotic was agreed at the 2010 Meeting of the International Scientific Association for Probiotics and Prebiotics (ISAPP) [98]. According to it prebiotics are defined as “A dietary prebiotic is a selectively fermented ingredient that results in specific changes, in the composition and/or activity of the gastrointestinal microbiota, thus conferring benefit(s) upon host health.”

Upon fermentation of these prebiotics by beneficial microorganisms under anaerobic conditions they produce Short Chain Fatty-acids (SCFA) like butyrate, acetate, propionate of varying quantities. At the end, it results in a decrease in pH and thereby preventing overgrowth of pathogenic bacteria, which are sensitive in nature and also micro biome has increased inulin) resulted in an increase of Lactobacilli & Bifidobacteria and decreases C. perfringens [61]. It has been shown to induce invasion of collagen gel by cell lines derived from colonic adenomas [62]. Furthermore leptin was also shown to extend the growth and proliferation of a colon cancer cell line, as proof by BrdU incorporation and c-fos expression [63]. Gut microbiota contribution

Intestine is composed of over 1000 different bacterial species and the microbial population is heterogeneous in nature. The microbial density within large intestine is 12-fold beyond that in the small intestine. So there is an estimated 12-fold increase in cancer risk in the large intestine compared with the small intestine [81]. It has been revealed that microflora resident in colonic region are able to convert...
and differentiation. Many cell communication pathways are also in regulation of various processes like apoptosis, cell proliferation, oncogenes as well as inactivating mutation in tumour suppressor genes. Tumorigenesis is a process that involves activating mutations in proto-oncogenes, contributing cancer as an endpoint [114]. As it is known that cancer can affect intestinal metabolic physiological conditions and thereby generation, building redox imbalance, and DNA damage, which of such difficult conditions might then cause uncontrolled free radicals. Colon tumorigenesis is a process that involves activating mutations in proto-oncogenes as well as inactivating mutation in tumour suppressor genes like p53, Adenomatous Polyposis Coli (APC) gene. These genetic events lead to changes in signal transduction pathways which are involved in regulation of various processes like apoptosis, cell proliferation and differentiation. Many cell communication pathways are also associated with colon tumorigenesis like APC, Beta-catenin protein [111]. Probiotic studies have clearly shown that microencapsulated Lactobacillus acidophilius preparation upon oral administration at a range of (10^5-10^6 cfu/ml) daily reduces the tumor size, multiplicity and cancer progression in mice model. This study showed that probiotic could be able to modulate the gene expression of APC in colonocytes [112]. Recent studies explored that L. casei and L. rhamnosus GG cell-free supernatants (CFS) are able to inhibit colon cancer cell invasion by influencing levels of the tight junction protein zona occludens-1 (ZO-1) and matrix metalloproteinase-9 (MMP-9) activity in cultured metastatic human colorectal carcinoma cells [113].

Colonic region of humans contain very diverse mixture of bile, mucus, desquamated epithelial tissue cells, various microorganisms and their fermentation products, undigested or unabsorbed food and their respective metabolic products like metals, salts, toxins, mutagens, carcino, and dissolved gases. It is assumed that enteric membrane is consistently challenged with diet- and other oxidants and carcinogens that are derived from bacterial source. Chronic exposure of such difficult conditions might then cause uncontrolled free radicals generation, building redox imbalance, and DNA damage, which can affect intestinal metabolic physiological conditions and thereby contribute cancer as an endpoint [114]. As it is known that cancer can initiate from the epithelial cells that line the bowel. These cells divide rapidly with a high metabolic rate and it might be responsible for increased oxidation of DNA [115]. Another hopeful approaches of preventing colon cancer is by decreasing the levels of H2O2, (hydrogen peroxide) as generally it involved in the development of various aspects of tumours like tumour progression,enhanced proliferation when compared to normal ones and increased spreading of cancer cells in colonic region. These types of processes can be modulated by increasing the levels of activity of catalase enzyme producing bacteria. If an adequate number of catalase enzyme producing bacteria proliferate in colonic region, then might be a chance of decreasing the colon cancer risk by increasing its antioxidant capacity and thereby decreases H2O2 levels in colonic region. Through this manner, it is possible to minimize the cancer cell growth and spread in colon. Lactococcus lactis is the potential strain which is involved in controlling colon cancer of such activity and experimentally proven in DMH induced murine model [122]. Another aspect of colon carcinogenesis might be due to association of bacterial enzymes like nitroreductase, β-glucuronidase, which are involved in transformation of pro-carcinogens into carcinogen [123]. Results in the experimental studies (a rat model study) show that upon supplementation of probiotic L. acidophilius, along with meat diet, which contain 72% beef, it is observed that there is a nearly 50% decrease in activities for faecal enzymes like β-glucuronidase and nitroreductase. Another research on L. acidophilus strain, through an experimental animal model study, also demonstrated that consumption of such strain leads to a decrease in faecal enzymatic activities like nitroreductase, azoreductase, and β-glucuronidase [124,125]. According to (Gorbach 2000) the suppression of bacterial enzyme activities like urease, β-glucuronidase, nitroreductase, hydrolase and tryptic activity was noted upon Lactobacillus GG administration [126].

It is well known that foodborne genotoxic compounds such as mycotoxins and plant glycodies or genotoxins created during food processing such as heterocyclic amines and polycyclic aromatic hydrocarbons are capable of expressing risk within the gut [127]. Mycotoxins, as an example, are carcinogenic fungal metabolites that contamine cereals meant for human consumption and feed for animal consumption. Dairy probiotics like Propionibacteria were shown to remove mycotoxins from aqueous solutions in vitro [128,129]. Dairy propionibacteria were also shown to bind cytoxins like microcystin-LR and heavy metals like lead and cadmium [130,131]. Therefore ingestion of such probiotic propionibacterium might reduce bioavailability and absorption of these carcino, and thus reducing cancer risk. Metabolic degradation of AFB1 by viable L.rhamnusos GG has been excluded as a possible binding mechanism,since heat- and acid-killed L.rhamnusos GG remove AFB1 even more effectively than viable bacteria [132]. The binding of carcinogen aflatoxin B1 by L.rhamnusos GG has been reported. It has been proposed that components will bond covalently to peptidoglycan mechanism,since heat- and acid-killed L.rhamnusos GG remove AFB1 even more effectively than viable bacteria [132]. The binding of carcinogen aflatoxin B1 by L.rhamnusos GG has been reported. It has been proposed that components will bond covalently to peptidoglycan mechanism,since heat- and acid-killed L.rhamnusos GG remove AFB1 even more effectively than viable bacteria [132]. The binding of carcinogen aflatoxin B1 by L.rhamnusos GG has been reported. It has been proposed that components will bond covalently to peptidoglycan mechanism,since heat- and acid-killed L.rhamnusos GG remove AFB1 even more effectively than viable bacteria [132]. The binding of carcinogen aflatoxin B1 by L.rhamnusos GG has been reported. It has been proposed that components will bond covalently to peptidoglycan mechanism,since heat- and acid-killed L.rhamnusos GG remove AFB1 even more effectively than viable bacteria [132]. The binding of carcinogen aflatoxin B1 by L.rhamnusos GG has been reported. It has been proposed that components will bond covalently to peptidoglycan mechanism,since heat- and acid-killed L.rhamnusos GG remove AFB1 even more effectively than viable bacteria [132]. The binding of carcinogen aflatoxin B1 by L.rhamnusos GG has been reported. It has been proposed that components will bond covalently to peptidoglycan mechanism,since heat- and acid-killed L.rhamnusos GG remove AFB1 even more effectively than viable bacteria [132]. It has been proposed that components will bond covalently to peptidoglycan mechanism,since heat- and acid-killed L.rhamnusos GG remove AFB1 even more effectively than viable bacteria [132].

To understand the mechanism of inhibition of colon carcinogenesis, experiments were conducted by using azoxymethane - a potential carcinogen generally used to induce colon cancer in rodents and the same also prompted aberrant crypt foci in rats. Inhibition of colon carcinogenesis was noted due to a stimulated growth of bifidobacteria in the colon. The growth of bifidobacteria leads to lowering of pH, which is attributed to further inhibit aberrant crypt foci, crypt multiplicity and growth of E. coli and clostridia in rats [135,136]. In addition, dietary ingestion of Bifidobacterium longum (lyophilised culture) showed that there is a significant suppression in tumor multiplicity as well as a decrease in the size of tumor volume. It also alters the intermediate biomarkers of colon cancer, thereby providing strong anti-tumor activity and in another study, it was noted that expression levels of ras-p21(onscoprotein) and cell proliferation in colonic mucosa cells.
was decreased. Upon addition of *B. longum* to the rat diet and thereby providing anti-tumor activity [137,138].

Probiotics like *Bifidobacterium* B12 and *L. plantarum*, have shown significant role in the anti-genotoxicity effect. Experimental evidence indicates that these two probiotics show decreased faecal water associated genotoxicity towards HT-29 cells, thereby proposing that above mentioned probiotics may be to prevent the initial stages of colon cancer [139]. In the context to the discussion, probiotics like *Bifidobacterium* spp, *L. helveticus*, *L. bulgaricus* and *S. thermophillus* have undergone an assay recently with HT29 colon epithelium cancer cell line and it was noticed that they or certain compounds produced by them interact with colonic epithelial cells directly and thereby growth rate is decreased and differentiation is induced [140]. Some studies observed that upon oral administration of *Lactobacillus salivarius* UCC118 in a placebo-controlled study, incidence of mucosal inflammation and colon cancer activity was decreased in IL-10 knockout mice by changing intestinal microflora, thereby it also decreased coliforms, enterococcus and *Clostridium perfringens* levels in the probiotic fed group [141].

Another possible reason for the onset of gut cancer risk is exposure of diet containing heterocyclic amines. In vitro studies demonstrating that certain strains of LAB are able to decrease food-borne carcinogens like heterocyclic amines (formed during cooking of meat at high temperature and is closely related to onset of colorectal cancer by means of producing byproducts upon fermentation by gut microbiota and thereby it causes DNA damage). Heterocyclic amines are found to have the greatest binding capacity. The extent of binding is dependent on mutagen and bacterial strain used and the binding was mostly due to the cation exchange mechanism. In addition some literature evidence shows that certain lactobacilli can degrade food-borne carcinogens like dimethylnitrosamine and diphenyl nitrosamines [82,142,143]. With reference to the food borne carcinogen, whole cells of bifidobacteria have also been found to bind with the mutagen-carcinogen 3-amino-1,4-dimethyl-5H-pyrido[4,3-b]indole, thus removing it via feces physically and subsequently reducing its absorption in intestinal lumen [144]. It has been noticed that supplementation of fermented milk with *L. acidophilus* is able to decrease the count of faecal putrefactive bacteria like coliforms and increase the count of beneficial microorganisms like lactobacilli in the intestine [145] (Figure 3 and Table 1).

**Bottlenecks/Future Challenges in Study**

Most of the positive outcomes given by the probiotic treatment are in observed form under experimental conditions. Future challenges are needed in the direction of standradising methodology to study effects. Long term safety studies of probiotics is also required. FAO/WHO jointly had proposed a guideline for recently identified/ less reported strain with no history of safe human use and strains that are not in the category of GRAS. For safety demonstration they have to undergo various in vitro and in vivo assessments and it also include toxicity studies like acute, sub-acute and chronic studies are also suggested for all newly identified strains which when taken in adequate amounts. To study dosage optimisation is required and also study the variability of effects in different category of persons such as aged groups, immunocompromised persons. For clinical studies
