Abstract

The novel features of engineered nanoparticles, such as multi-wall carbon nanotubes (MWCNTs) are impressive and attractive for technology, however they dissolved in water and accumulate in soils through the application of sewage sludge, accidental spills, and deposition from the air, agrochemicals or soil remediation. Given that several studies have revealed that chronic exposure to these nanomaterials products through the ingestion of drinking water, inhalation and dermal contact may harbour potential risks to human health, risk assessment of these materials in the aquatic environment is becoming essential. Here we propose a freshwater invertebrate, the leech Hirudo medicinalis, as a model to assess the effects MWCNTs on the immune system by means of in vivo and in vitro experiments. For this study, we used a consolidated experimental approach based on injection in the body wall of the leech of the biomatrice Matrigel (MG), added with a specific macrophage chemotaxant, the cytokine Allograft inflammatory factor-1 (AIF-1) and/or with MWCNTs. MG sponges analysis show the presence of a larger number of cells positive for both CD68 and HmAIF-1, specific monocyte-macrophage markers. Ultrastructural analysis suggests that MWCNTs may be internalized by phagocytosis but they seem also to be able to pierce cell membranes during cells migration.

Cells extracted from MG were also used for in vitro treatment with MWCNTs at different concentration (2.5, 5, 10, 25, 50 and 100 µg/ml) for 24 h to study cell morphology changes and production of amyloid fibrils in order to encapsulate the foreign bodies. Our results, not only confirm the ability of MWCNTs in inducing a potent inflammatory response, but highlight rapid colorimetric assays that can be successfully used as sensitive tools for aquatic pollution biomonitoring.

Keywords: Multi-wall carbon nanotubes (MWCNTs); Hirudo medicinalis; Macrophages; Matrigel; Innate immune response; Amyloid fibrils

Introduction

The rapid development of nanotechnology and nanoscience during the last decade has led to the discovery of nanomaterials such as carbon nanotubes, classified into single-walled (SWCNTs) and multi-walled (MWCNTs) carbon nanotubes, which have several potential applications. The former are mainly used in biology and medicine [1], while the latter are widely used in industry, and their applications are increasing constantly in particular in waste water treatment [2]. Due to their massive production and in the light of the most recent studies, which emphasize the potential toxicity of nanotubes, it is more than ever necessary to take into account their impact on the environment [3]. Aquatic ecosystems seem to be particularly susceptible to contamination by MWCNTs and other pollutants with harmful consequences for the organisms that inhabit them. Several studies, in fact, demonstrate MWCNTs toxicity and bio-persistence within tissues and cells [4-6]. The bioaccumulation of MWCNTs in aquatic animals may as well represent a risk to humans, who may be exposed to this nanomaterial through many pathways, such as inhalation, injection, penetration but also ingestion [7]. In particular several studies revealed that the physical dimension of MWCNTs are critical factors in mesothelial injury and carcinogenesis [8] and are associated with phagocytosis [9] that leads to the production of pro-inflammatory cytokines and reactive oxygen species (ROS) [10]. Although the literature abounds with studies on MWCNTs toxicity, the existing toxicological data are still fragmentary and their biological interactions with cells, proteins and tissues have not yet been fully understood [3].

The aim of this work is to develop and optimize approaches to suggest an invertebrate animal model able to give rapid and sensitive responses upon the presence of pollutions in water, such as nanoparticles, even if at low concentration. Immune system of organisms represents a sensitive physiological indicator that may be affected even at low concentrations of nanomaterial exposure; however the animal models usually employed in ecotoxicological studies are not suitable due to their immune responses strictly linked to their bauplan.

The model organism chosen in this study is the leech Hirudo medicinalis. This aquatic invertebrate is suitable for experimental manipulation, economic, easily treated and without significant ethical considerations related to use and regulatory restrictions. Leech is a new interesting animal model for several reasons: i) its immune response processes includes the same steps described for vertebrate [11-15], involving similar cellular mechanisms and key molecules that play pivotal roles for guiding and regulating the hematopoietic cells activation and differentiation, revealing a conserved regulation immune response processes; ii) any response evoked by different stimuli are activated within a short period of time (6, 24 hours) and clear and easily detectable due to their small size and anatomical

simplicity; iii) it shows an added value related to a novel developed assay based on the use of a biomatrix (MATRIGEL) [16-18] to obtain in vitro expansion of macrophages primary leech cells implicated in immune response process that could be used to test the effect of the nanomaterial on immune cells.

Our combined experimental approaches, based on high sensitive inflammatory response and rapid colorimetric tests, can highlight adverse effects of MWCNTs on immune system cells, even at low concentration, and could be used as quick sensitive tools for aquatic pollution bio-monitoring.

Materials and Methods

Animals and treatment

Leeches (H. medicinalis, Annelida, Hirudinea, from Ricarimpex, Eysines, France) measuring 10 cm were kept in water at 19–20°C in aerated tanks. Animals were fed weekly with calf blood. Animals were randomly divided into separate experimental groups according to different protocols and treatments. Each treatment was performed at the level of the 20th metamere. Before each experiment, leeches were anesthetized with a 10% ethanol solution.

Group 1: Leeches injected with 300 µl of liquid MG (an extract of the murine Engelbreth–Holm–Swarm (EHS) tumor produced as previous described [19]) served as controls.

Group 2: Leeches (five animals/condition) injected with 300 µl of liquid MG supplemented with 100, 150 and 300 ng of the recombinant protein rHmAIF-1 (kindly donated by Jacopo Vizioli and Francesco Drago, University of Lille, France), were used to selectively isolate the macrophages cells migrating under the influence of HmAIF-1. The best concentration of rHmAIF-1 required to induce significant cell migration was 300 ng and was used for the next experiments.

Group 3: Leeches injected with 300 µl of liquid MG supplemented with 20 µg of Multi-walled commercially available and industrially employed Carbon Nanotubes (MWCNTs), NANOXYL™ NC7000 (Belgium NANOXYL, Sambreville; average 9.5 nm diameter by 1.5 µm mean length with surface area of 250-300 m²/g, not functionalized, manufactured by catalytic carbon vapour deposition (CCVD) process, with a purity of 90%). For these experiments, the pristine MWCNTs were used directly without any chemical processing before use. This concentration of MWCNTs was necessary to obtain visible aggregates in the Matrigel pellet.

Group 4: Leeches injected with 300 µl of liquid MG supplemented with 300 ng rHmAIF-1 and 20 µg of MWCNTs.

Animals were sacrificed after 1 week. MG implants were removed from the animal and processed in different ways depending on the type of analyses.

Transmission electron microscopy (TEM)

MG implants for routine transmission electron microscopy (TEM) were fixed in 2% glutaraldehyde in 0.1 M sodium cacodylate buffer (pH 7.2) for 1 hour at room temperature. Specimens were washed in the same buffer and then post-fixed for 1h with 1% osmium tetroxide in cacodylate buffer at room temperature. After standard dehydration in ethanol series, specimens were treated with propylene oxide/ Epon-Araldite (1:1) for 1 hour and then embedded in an Epon-Araldite 812 mixture. Sections were obtained with a Reichert Ultracut S ultratome (Leica, Nussloch, Germany). Thin sections (80-90 nm) were stained by uranyl acetate and lead citrate and observed with a Jeol 1010 EX electron microscope (Jeol, Tokyo, Japan). Images were acquired with digital camera Morada, Olympus (Tokyo, Japan).

Colorimetric and indirect immunofluorescence staining

MG implants were embedded in Polyfreeze tissue freezing medium (Polysciences, Eppelheim, Germany) and immediately frozen in liquid nitrogen. Cryosections (7 µm) were obtained with a Leica CM1850 cryotome and slides were immediately used or stored at -20°C.

For colorimetric assays, cryosections were immersed in distilled water and incubated with May Grunwald Giemsa differential staining (Bio Optica, Milano, Italy), which permits identification of hematopoietic cells based upon their cytoplasmic pH properties.

For Thioflavin-S method, samples were treated with Mayer’s hemalum for 2 minutes. After washings with water samples were stained with 1% Thioflavin-S in aqueous solution. After further washing, they were treated with 1% acetic acid for 20 minutes. This method stains the amyloid fibrils in green/yellow fluorescence.

For indirect immunofluorescence, samples washed with PBS were pre-incubated for 30 min with PBS containing 2% bovine serum albumin (BSA) before the primary antibody incubation for 1 hour at room temperature. The primary antibodies (diluted 1:200) used were: rabbit anti-human CD45 (GenScript, USA), which reacts with leech hematopoietic precursors cells, rabbit anti-human CD68 (Santa Cruz Biotechnology, USA), which reacts with leech macrophages, as previously demonstrated [14], and rabbit anti-Hm-AIF-1 (kindly donated by Jacopo Vizioli and Francesco Drago, University of Lille). The washed specimens were incubated for 1 h at room temperature with an anti-rabbit secondary antibody (Jackson Immuno Research Laboratories, USA) Cy3 conjugated (dilution 1:200). After further washing with PBS, cryosections were incubated for 10 minutes with the nuclear marker DAPI (4',6-diamidino-2-phenylindole). The slides were mounted in Citifluor (Citifluor Ltd, London, UK) with coverslips and observed by light and fluorescence microscopy Nikon Eclipse Ni (Nikon, Japan).

The staining was visualized using excitation/emission filters of 490/525 nm for Thioflavin-S, 550/580nm for Cy3 and 360/420 nm for DAPI. Data were recorded with Nikon Digital Sight DS-SM (Nikon, Japan) digital camera. Images were combined with Adobe Photoshop (Adobe Systems, Inc.). In control samples, primary antibodies were omitted and sections were treated with BSA-containing PBS.

In vitro matrigel assays

After 1 week in vivo (corresponding to a suitable cell concentration for seeding) rHmAIF-1 supplemented MG implants were harvested and cultured. Each implant was minced in small pieces using sterilized razor blades and plated in wells of 60 mm in diameter in DMEM medium (Celbio, Milan, Italy) modified by dilution (1:4) to reach iso-osmolality and supplemented with 1% glucose, 10% fetal bovine serum and 1% gentamicin [16]. Cells were maintained at 20°C and histologically and immunocytochemically examined 1 days and 1 week after seeding.

All cultures were performed in triplicate and scored at 1 week from seeding with an inverted Olympus microscope (Tokyo, Japan). Data were recorded with a DS-5M-Li digital camera system (Nikon).

Assessment of cell viability with trypan blue

Cell viability was assessed using the vital dye Trypan blue, which is incorporated only in dying or dead cells. The cells were incubated at
room temperature for 5 min with 0.4% trypan blue solution (diluted 1:1 in basal medium) and directly observed using an inverted optical microscope (Olympus).

In vitro MWCNTs treatment

Cells were cultured on a round coverslip in 24 wells plate for 1 week before MWCNTs treatment. MWCNTs powder was weighed re-suspended in culture medium and then sonicated 15 min for 2 cycles in an ultrasonic bath (starsonic 35, Liarre, Italy) to avoid particles aggregation. MWCNTs were administrated at 2.5, 5, 10, 25, 50 and 100 µg/ml for 24 h. Particle exposure concentrations were chosen upon assessment of existing literature concerning exposure of vertebrate macrophages cell lines to MWCNTs and SWCNTs [3]. Cells were then fixed with paraformaldehyde 3% for 10 minutes and washed in PBS before proceeding with immunocytochemical and colorimetric assays described above.

Statistical analysis

Cells extracted from matrigel pellet were plated out in 60 mm diameter at a density of 1000 cells/well and counted after one week from seeding, using the Image J software package. Five fields for each time lapse (1 day and 1 week) were analyzed and the number of counted cells is referred to the total area of the well. Statistical significance was assessed by an unpaired Student’s t test using Origin 5.0 software (Microcal).

Results

Morphological, immunocytochemical and colorimetric characterization of cells infiltrating the MG sponge

Light and trasmission electron microscopy: First, since MG can be supplemented with different concentrations of cytokines, we sought the best rHmAIF-1 concentration for the macrophages tissue cells recruitment in the biomatrix. We supplemented 300 µl of MG with 100, 150 (data not shown) and 300 ng of rHmAIF1 and the MG pellets, formed following inoculation, were recovered and processed for standard histology one week after injection. While cellular infiltrates were not observed in control MG samples (Figure 1A), the number of cells migrating in the biomatrix increased in relation to the rHmAIF-1 concentration with the highest cell density obtained with 300 ng of rHmAIF-1 in the MG (Figure 1B). In order to assess the interaction between MWCNTs and cells migrated in the MG pellet, we used the biopolymer matrigel supplemented with both rHmAIF-1 and MWCNTs. Numerous migrated cells were visible in the MG sponge,
most forming a clot around the large MWCNTs aggregates (Figure 1C). Migrating cells, even if in a reduced number, was present in the MG pellet supplemented only with MWCNTs (Figure 1D). Cells coloured with the May Grunwald Giemsa differential staining showed dark blue nuclei typical of monocyte and macrophages cell lines (Figure 1E-1H).

Ultrastructural analysis at TEM showed that in MG supplemented only with rHmAIF-1 cells appear either round or with an irregular shape with a cytoplasm rich in electron-dense granules, with a pronounced migratory phenotype showing pseudopodia and an active degradation of the surrounding matrix (Figure 1I and 1J). Cells migrated in MG pellet supplemented with MWCNTs, visible dispersed throughout the MG sponge or grouped in aggregates (Figure 1K and 1L), showed increased membrane ruffling and lamellipodia associated with phagocytosis (Figure 1M). Moreover, particulate acquisition was evident as engulfment of particles settled in vesicles or in the cytoplasm (Figure 1N and 1O).

Immunocytochemical characterization: In order to better characterize the cells infiltrating the MG and surrounding the MWCNTs aggregates, the Matrigel pellets were removed from the leech after one week from injection and sections of the biopolymer were immunostained with antibodies to macrophage cell markers. The cells infiltrating the Matrigel sponge, either supplemented with only the rHmAIF-1 protein, with both rHmAIF-1 and MWCNTs or with only MWCNTs, were strongly positive for the antibodies anti-CD68 (Figure 2A-2C) and anti-HmAIF-1 (Figure 2D-2F). In particular, in the MG containing MWCNTs, numerous infiltrating CD68+/HmAIF-1+ macrophages reached and surrounded the MWCNTs aggregates (Figure 2B, 2C, 2E and 2F). No signal was detected in negative control experiments where primary antibodies were omitted (Figure 2G).

Thioflavin-S staining for amyloid fibrils detection: Since recently has been demonstrated that MWCNTs aggregates induce macrophage recruitment, tissue inflammation and amyloid deposition in mice [20], we performed a Thioflavin-S staining on MWCNTs supplemented MG sponges to reveal the presence of amyloid fibrillar material. Thioflavin-S positivity was found in the macrophages surrounding the aggregates of MWCNTs, indicating that these cells were implicated in the production and deposition of amyloid fibrils (Figure 2H and 2I).

Cultured Cells and MWCNTs in vitro treatment

In order to obtain primary cultures of leech macrophages cells, the MG polymers supplemented with rHmAIF-1 was removed from the leeches after 1 week in vivo and the cells placed in culture. Starting from day 1 after seeding, cultured cells were present as clusters (Figure 3A and 3B). One week after seeding, cultures were formed by an increased number of cells (Figure 3C). To determine the growth and viability characteristics of the cultured cells, the cells from the matrigel polymers that had been removed from the leeches after 1 week in vivo, were plated at a density of 1000 cells for each well, and the number of...
cells were counted after one week from seeding. As shown by statistical analysis the number of cells increased by 2.5 times (Figure 3D). Trypan blue exclusion demonstrated that these cells were still viable (data not shown), exhibited the same morphological aspects described for the cells within the MG in vivo (Figure 3E), were positive for May Grunwald Giemsa differential staining (Figure 3F) and expressed the leukocyte-specific marker CD45 (Figure 3G), and the macrophage markers CD68 (Figure 3H) and Hm AIF-1 (Figure 3I). No signal was visible in negative control sample (Figure 3L). Moreover these cells showed a weak positivity for Thioflavin-S dye (Figure 3M).

After obtaining primary culture of macrophages, we evaluated their ability to produce amyloid fibrils after MWCNTs exposure (Figure 4A-4X). CD45+ (Figure 4A-4F) and Hm AIF-1+ (Figure 4G-4L) macrophages incubated for 24 h with increasing concentrations of MWCNTs (2.5, 5, 10, 25, 50 and 100 µg/ml) were highly positive for Thioflavin-S staining. The amyloid fibrils stained in yellow (Figure 4M-4R) were accumulated in large dilated reticulum cisternae filled with spatially organized fibrillar material, as visible by ultrastructural analysis at TEM (Figure 4U) and then released in the extracellular environment (Figure 4T). Combined fluorescence/transmission images clearly showed that Hm AIF-1+/CD45+ macrophage cells (Figure 4V and 4W), strictly associated to MWCNTs aggregates, produce amyloid fibrils Thioflavin-S' (Figure 4S and 4T).

**Discussion**

The contamination of water by various different pollutants is a serious problem worldwide in terms of human health and agriculture. MWCNTs are currently attracting intense research efforts because of their unique properties, which make them suitable for many industrial developments, applications in biomedicine, nanoelectronics, mechanical engineering, personal care products and textiles. MWCNTs are currently also produced and used in industry on a large-scale, increasing the risk for a widespread human and environmental exposure. Data in literature [21] have demonstrated that these nanoparticles have a very long half-life in vivo, could affect cellular functions at molecular levels and are capable of penetrating physiological barriers to reach vital organs inducing chronic inflammation, which it is often associated with insurgence of cancer. The physical dimensions and the biopersistence of MWCNTs were found to be similar to asbestos, and they indeed have revealed asbestos-like pathogenicity [22,23]. In order to avoid making the same mistakes, more research must be done on these new and emerging products in the market to provide a complete understanding of biological properties of MWCNTs, including uptake, distribution, intracellular trajectory, interactions with the immune system.

We have recently observed that in vivo treatment of *H. medicinalis* with water dispersed MWCNTs induce toxic effect also at low concentrations and after a short time of exposure. The
findings corroborate the observations of other authors on vertebrate macrophages [29-31]. Moreover, since recent experimental studies show that carbon nanotubes influence the aggregation process of proteins associated with neurodegenerative diseases like amyloid fibril production, we evaluate, by using the colorimetric methods of Thioflavin-S [32], the MWCNTs ability to induce amyloid deposits in correspondence of MWCNTs/macrophages associations [20]. Several studies demonstrated in fact that nanoparticles that enter cells by diffusing through cell membranes or by active uptake, such as endocytosis [33], cause toxic effects such as the formation of reactive oxygen species (ROS) [5,8,34]. Oxidative stress can induce proteins to adopt an insoluble beta-pleated sheet conformation [35], and according to numerous authors [36-40] oxidative damage appears to be the earliest events preceding amyloid fibril formation. Thus, we evaluate the amyloid fibril production from macrophage in relation to MWCNTs exposure. As expected, we found a massive accumulation of fibrils Thioflavin-S, associated to the macrophages forming a scaffold around the MWCNTs aggregates. The presence of these fibrils in MWCNTs and rHmAIF-1 supplemented MG confirms the strong reaction of macrophages to the nanomaterial.

Starting from these results, the next target of our work was to obtain in vitro expansion of macrophages primary leech cells that could be used as a sensitive method to evaluate the presence of the nanomaterial in contaminated water. We used the biopolymer MG supplemented with rHmAIF-1 as a vector to isolate these cells in vivo and then culture them obtaining an in vitro expansion of macrophages primary leech cells. Seven days after seeding cells cultured in a normal medium expressed the same specific macrophage markers (CD45, CD68, HmAIF-1) as that already observed in vivo. The ability of MWCNTs to induce amyloid fibrils generation were assessed by measuring Thioflavin-S fluorescence as a reporter of amyloid fibrils generation. As compared with control unexposed cells, a significant increase in Thioflavin-S staining was observed in exposed macrophage cell in concentration independent manner and the amyloid fibrils formed
a scaffold around the MWCNTs aggregates, indicating that amyloid deposition might be a barrier to contain non-self-material.

Recent data on murine model [20] showed inflammatory responses generated by commercially available nanotubes that are inhaled. Moreover, literature is beginning to show data concerning the potential risks to public health and the aquatic environment when these nanomaterials are dispersed in water. Our data on leeches confirmed the toxicological effects of nanotubes. The use of annelids to implement the data so far produced is in order to demonstrate the reliability and reproducibility of the new model in respect to those commonly utilized by eco-toxicologists. In fact, unlike other invertebrates, H. medicinalis use the same strategies and the same molecules of vertebrates in response to different stimuli. For these reasons, it is critical to investigate the question of the nanomaterial safety utilization new models and methods for assessing the environmental risks of these possible toxic particles.

The data produced by this project will be a cornerstone in determining the potential toxicity of MWCNTs and the eventual precautions needed in the wastewater discharge. Our results also provide critical information to regulatory agencies and industry to determine the need for monitoring and regulation regarding MWCNTs.
