Abstract

Ectopic thyroid tissue is a rare congenital anomaly with extremely rare occurrence of dual ectopy. Authors present a case of a 13 year-old girl with anterior neck swelling since one year. Contrast enhanced CT demonstrated absence of normally located, bilobed thyroid gland. Instead two foci of ectopic thyroid tissue were seen in the lingual and pretracheal region. Imaging workup is of great value in diagnosing this rare entity.

Keywords: Ectopic thyroid; Dual thyroid ectopy; Anterior neck masses; Neck swelling

Introduction

Ectopic thyroid tissue (ETT) is a rare congenital anomaly defined as the thyroid tissue not located in its normal position anterio-lateral to 2nd–4th tracheal cartilage [1]. In 1869, Hickman reported the first case of ectopic thyroid tumor at the base of tongue, pressing down the epiglottis on the larynx and causing death by suffocation sixteen hours after birth [2]. The prevalence of ETT is about 1 per 100000–300000, however, autopsy studies revealed its prevalence approximately 7-10% [1] mostly affecting women with a female/male ratio of 4/1 [3].

ETT most frequently affects women and although a congenital anomaly, it is usually detected at adolescence and during pregnancy due to increased physiological demand for thyroid hormones [1]. ETT may occur anywhere along the path of its initial descent from the foramen cecum to its final pre-tracheal position [1]. The most commonly found ETT is at the base of tongue (lingual thyroid) with incidence of approximately 90% of reported cases [1]. In 70–75% of cases, lingual thyroid is the only thyroid tissue present [4].

Other rare sites are: sublingual or higher cervical region, trachea, mediastinum [1], lung [4], heart [4] and paracardiac area. Extremely rare locations are ovaries, adrenals, gallbladder, pancreas, duodenum, small bowel mesentery, pituitary fossa, sphenoid sinus, uterus, Axilla, palatine tonsils, iris of eye [2], vagina [2], Parathyroid glands, cervical lymph nodes, submandibular glands, carotid bifurcation, esophagus and skin [3].

Dual and Triple Ectopies

Multiple (dual and triple) ETT is very rare and few cases have been reported in literature [5]. In most cases of dual ectopia, the first lesion is lingual or sublingual and the second is subhyoid, infrathyroid or suprathyroid. Dual ETT in porta hepatitis and the tongue has also been described [4]. Dual ectopic thyroid with a normally located pretracheal thyroid is extremely rare [6].
Figure 1a: Axial non-enhanced CT section at lingual base showing a well-defined, rounded, slightly hyper dense lesion. Figure 1b: Non-enhanced axial CT section below the level of the larynx anterior to the trachea showing a low attenuating round lesion. Fine needle aspiration cytology (FNAC) is the only modality to differentiate between a benign and malignant lesion [4]. Other investigations may be required depending on the location of ETT. Echocardiography and coronary angiography may be necessary in intra-cardiac thyroid ectopy, while barium swallow is important in some patients presenting with dysphagia [2] (Figure 2). Secondary involvement and malignancy potential

All diseases capable of affecting the normal thyroid can affect the ectopic thyroid as well, like adenoma, hyperplasia, inflammation and malignancy. The rate of malignant transformation in ectopic thyroid is no greater than in normally placed thyroid [6]. Primary thyroid carcinomas arising from ectopic thyroid tissue are uncommon and have been reported in cases of lingual thyroid, thyroglossal duct cyst, lateral aberrant thyroid tissue, mediastinal and stroma ovarii [4] (Figure 3).

Figure 2b: Axial enhanced CT section just below the level of the larynx showing an intensely enhancing round soft tissue lesion. Figure 3: Sagittal section through the midline of the neck revealing both sublingual and pretracheal ectopic thyroid tissue. Management

Management is controversial. No treatment is required for asymptomatic lingual ETT with euthyroid state but patient should be followed for development of any complications. However due to capability of malignant transformation, some authors consider complete surgical removal of ETT as an appropriate treatment [7]. Conclusion

ETT is a rare entity with majority of cases located at the base of tongue. Dual and triple ectopies are extremely rare. The majority of patients are asymptomatic; however, symptoms may arise following enlargement of the gland during periods of stress. Scintigraphy, ultrasound, CT scan, MRI, biopsy and thyroid function tests are the main diagnostic tools.
