Abstract

Echinococcosis/hydatidosis is a zoonotic disease. The disease is caused by adult worms and larval (metacestode) stages of the taeniid cestode Echinococcus granulosus. The life cycle is completed into two hosts. The final host usually carnivore e.g. dog, and the intermediate host usually herbivorous and man. The aim of this study is to evaluate the fertility of cysts and viability of protoscoleces in man and camel hydatid cysts in order to determine the prevalence of their fertility and to study the association with variables typical of host and of the parasite.

Material and methods: Across-sectional and observations study was done in biological material (the fluid from human and camel hepatic and lung hydatid cysts). The viability criteria used were ovoid form invaginated scolices and intact calcareous corpuscles. The presence of vibrating movements, and the absence of “vital” staining, the cysts were grouped in diameter cysts from small cysts to very large size of cysts. Descriptive statistics were for the calculation of the prevalence of fertility, analytical statistics for comparison of groups, and multivariate analysis for examination of the association between cyst fertility and clinical variables.

Results: A total of 99 cysts with less than 2 cm (7.8%), from 2-6 cm (81.2%), medium diameter 6-10 cm (57.8%), and more than 10 cm (7.8%), and prevalence of general fertility 68%, sterai cysts was 6%, supportive was 10% and calcified was 15%. Most of camel fertile cysts had medium size (81.2%), while the lowest rate belongs to the small cysts (7.8%). There was significant relationship between fertility of the cyst, type of infected organs, type of animals and size of cyst. Association with location, type, and diameter of the cyst, the viability Protoscoleces was assessed by microscopic observation of biological feature represented by muscular movements, flame cell activity in 0.1% aqueous eosin stain.

Conclusion: The differences between prevalence rates, the fertility of hydatid cysts and diversity sites localization observed in humans and camels. Fertility is associated with the type of cyst, location type, type of animal and size of cyst.

Keywords: Hydatidosis; Field investigation; Hydatid cyst; Sudan

Introduction

Cystic Echinococcosis (CE)/Hydatidosis is one of important zoonotic diseases caused by larval stage of the dog tapeworm, Echinococcus granulosus. Hydatid disease is most extensively found in East and North Africa, India, Australia, New Zealand, South America, and Middle East including Iran [1-9]. Mostly the rate of the infection in carnivores such as dog and herbivores such as sheep, camels are significant but humans also get the infections accidentally [10-16], hereby, hydatidosis is a major health-economic problem, that has become one of the WHO’s active plans for controlling the disease [17].

Larval in man caused hydatid disease, adult worms are only seen in definitive host, dogs, and they cannot develop in man. When the ova are ingested by a suitable intermediate host, they hatch in the duodenum and the oncosphere migrates to the blood stream where it is carried to the liver and others organs of the body. Here it develops into hydatid cyst which consists of an outer thick laminated cyst wall and an inner layer, from the inner layer blood capsules are produced which contain protoscoleces. Fertile hydatid cysts with viable protoscoleces in intermediate hosts are important factors in transferring infection, and stray dogs that wandering around abattoirs; spread the disease due to feeding on infected organs. These factors which differ according to the geographical situation, host and type of infected organs, effect on Echinococcus cycle persistence [17]. Therefore the aim of this survey was to evaluate the fertility of hydatid...
cysts and viability of their protoscoleces based on the site, size and type of cysts in slaughtered animals in Tambool, central eastern region of Sudan.

Rationale

Hydatidosis is known to occur in Sudan in man as well as animals, but the extent of the disease in human population is not known. This is mainly due to the nonspecific clinical presentation and the nonexistence of a sensitive and specific diagnostic methods, a part from confirmation at operation. Therefore this study was undertaken to study the epidemiology of the disease among the human population and to extract antigenic constituents from hydatid cysts in man and attempt to analyses them and use them as targets for different serological tests for the laboratory diagnosis of hydatidosis in man.

Objectives

To carry out the field investigation of hydatidosis/Echinococcus in Tambool area (The Central Region) and man at hospitals of Khartoum state.

Specific objectives:

To collected the cysts from internal organs (liver, lungs and other organs) and removed the tissue by scalpel, washed by normal saline five times, aspirate the fluid by syringing in tube 50ml and centrifuged to separate the protoscoleces and large particle.

Materials and Methods

Study design

It is an observational, cross sectional study, was done in biological material (the fluid from human and camel hepatic and lung hydatid cysts).

Study area

The study was conducted in Tambool town market (Central Eastern of Sudan) which is located 150 Km South East of Khartoum. At butane area is part of the Central rain lands that provides good grazing for camels, sheep, goats, and cattle stretches from the Ethiopian border in the East to Gezira State in the West roughly occupying the area between isohyets 400 and 700 mm. It comprises 120,000 square kilometers and lies between latitude 13.5°-17.5° N and longitude 32.4°-36.0° E. It is situated in the rich savanna environment, and second area at hospitals in Khartoum state, and other private clinics.

Fourteen cases were aspirated (10 liver aspirates, 2 lung aspirate, one abdominal aspirate and a spleen aspirate) (Table 2). Out of the 8 male samples, 2 were found positive while out of the 6 female samples, 2 were found positive. One from the two positive females aged 16 years with a large cyst (9.8 × 9.6 × 8.9 cm) in the right lobe. This was detected by CT scan. The other female was 42 years old with a lung hydatid cyst. The age group of the other patients ranged from <15 to >60 (Table 3).

Table 3: The location of hydatid cyst against age group.

From 8 patients in Khartoum state there were 2 patients positive for hydatid disease. One of 2 patients from Elgedarif state had hydatid cyst in the liver while one 14 year old boy from Elgezira state had hydatid cyst in the lung. All cases from southern and western Darfur were negative for hydatid cyst (Table 4). The 4 positive cases were fertile and viable for protoscoleces.

Table 4: The location of hydatid cyst in different organs.

Examination of cyst fertility & viability of protoscoleces

The pressure of the cyst fluid was reduced by using a sterile hypodermic needle. Then the cyst wall was transformed to sterile container and examined microscopically 40x for the present of protoscoleces. Similarly, the germinal layer was put in glycerin between two microscopic glass slides and examined for the presence of protoscoleces. Cysts which contained no protoscoleces as well as heavily suppurative or calcified were considered infertile. Fertile cysts were subject to viability test, drop of the sediment containing protoscoleces was placed on the microscopic glass slide and covered with a cover slip and observed for amoeboid like peristaltic movements with 40x objective. The viability of protoscoleces was tested for each fertile cyst per human camel and organ. For clear vision a drop of 0.1 aqueous eosin solution was added to equal volume of protoscoleces, of hydatid fluid on slide with the Principle that viable protoscoleces should completely or partially exclude the dye, while the dead ones taken up (Figure 1).

Most of camel fertile cysts had medium size (81.2%), while the lowest rate belongs to the small cysts (7.8%). There was significant relationship between fertility of the cyst, type of infected organs, type of animals and size of cyst (Table 5).

Table 5: Fertility rate of hydatid cysts and viability of protoscoleces of fertile cyst recovered from different organs of camel at Tambool slaughter house.

Also significant difference was observed between viability of camel (lung and liver) cyst protoscoleces (64.9% and 4.0%) respectively. The highest and lowest viability rate seen in small and high size of the cyst. Calcified cysts 15 (15.1) and suppurative cysts 10 (10.1) were the most common type of cysts (15.1%), and sterile were least (5.1%), fertile and suppurative cysts allocated the highest percentage of infection. The highest rate of fertility was revealed in camel lung (64.6%), and the lowest in the liver (4.0%). Most of sterile, suppurative and calcified cysts were found in camel lung (30.3%), and least were found in the liver (5.1%) the fertility cysts rate and viability of protoscoleces show in (Table 6).

Table 6: The viability of protoscoleces of fertile cyst recovered from different organs of camel at Tambool slaughter house.

Interpretation and discussion

The study found that the intermediate hosts were involved in the infection of hydatid disease at various rates. Human was the main intermediate host in the study area. The highest incidence was recorded in the liver (100%) and the lowest incidence was recorded in the lung (66.6%). The results also showed the high rate of infection in the liver (90%) and the lowest in the lung (66.6%). The results of the study are in agreement with the results of previous studies in the study area and other areas of Sudan.

In conclusion, the study suggests that hydatid disease is still a significant public health problem in the study area, and that efforts should be made to control the infection and prevent its spread.
immunological procedures. Imaging methods are sometimes limited to identify the germinal layer epithelium in the form of a brown capsule or the presence of protoscoleces. In addition, the highest percentage of cysts were reported as an intermediate host, indicating its importance for the transmission of Echinococcus granulosus in Central Sudan, for about 26.5% of camels examined in the study area [29,30].

In conclusion can be said that fertility rate of liver and lung hydatid cysts of camel and viability of protoscoleces is considerable. In addition, the fertility of hydatid cysts in human was low but they had high viability rate of protoscoleces. Fertility is associated with the type, location and the size of cyst.

### Author’s Contribution
Albadawi collected hydatid cyst samples from Tambool slaughter house, and examined macroscopic and microscopic of the cysts. Saad designed the experiment and prepared the final manuscript, Ahmed edited and helped with experimental design, Nawal analyzed the sequences and designed the study, Elowani and Daffalla edited the sequences and helped with experimental design, Teaser designed the experiment. All authors read and approved the final version of the manuscript.

### Acknowledgement
Authors would like to thanks the colleagues who helped me in performing this study particularly to Ibrahim Elhag Elmahdi, and Abdelmoneim Elhag Elmahdi, for their kind contribution in institute of Nuclear Medicine, Molecular Biology and oncology, University of Gezira, Wad Medani, Sudan. Surgeons in Khartoum hospitals for their cooperation for collecting hydatid cysts samples, this study was made possible by invaluable assistance provided by Mr. Hatim babaker polio, National Public Health Laboratory (NPHL). The authors are very grateful to Mss. Aida Mohammad Khair and Mawaheb Abdelmoneim Mycology department, Khartoum University.

Cystic Echinococcus (CE) occurs in all continents including circumpolar, temperate, tropical and subtropical and zones ranks in some areas as the leading disease of public health significance [19]. Camel appear to play the major role for the maintenance of E. granulosus in Central Sudan, for about 26.5% of camels examined in this study were found to be infected with cystic *Echinococcus* with high fertility rate (68%). Moreover, molecular characterization indicated that camel strain (G6) is more prevalent in this area. Since it had been found in camel, however, in all countries where camel has been reported as an intermediate host, it was too important for the local maintenance of the life cycle [19]. For all examined hydatid cysts, there were significant relations between the type of animals and infected organ with type of cysts. In addition the highest percentage of infection belonged to sterile cysts while calcified cysts possessed the least (Table 6). The presence of protoscoleces either attacked to the germinal layer epithelium in form of brown capsule or either presence in the cyst fluid was considered as indicative of fertility [27].

Two studies of protoscoleces was assessed by the mobility of flame cells together with the staining with 0.1 aqueous eosin solution [28]. Furthermore infertile cysts were further classified as sterile characterized by their smooth inner lining usually with slightly turbid fluid in its content. Typical calcified cyst produce a gritty sound feeling up on incision [29,30].

In agreement with our findings [31], in northwestern Ethiopia, the reported the sterile cysts as the most prevalent type of removed hydatid cysts [31,32], Additional [32], in Arak province of Iran, found calcified cysts as the least type among all hydatid cysts [31], however opposite to our finding, in Sardinia (Italy) calcified cysts were observed as the most prevalent [33]. In our statistical analysis showed a significant relation of cysts, fertility and their size. Most of fertile hydatid cysts had a medium size in camel lungs (Table 6).

In one case of human cystic Echinococcosis in the Netherlands the Argentinian molecular analysis of Echinococcus granulosus isolates encountered from man intermediate host showed for the first time that the camel strain genotype (G6) is infective for human [34-36]. Another study carried out in Mauritania identified the camels strain genotype (G6) in two human samples.

Although the literature reporting the presence of protoscoleces or their mobility in the cyst fluid, the viability of protoscoleces was assessed by the mobility of flame cells together with the staining with 0.1 aqueous eosin solution [28]. Furthermore infertile cysts were further classified as sterile characterized by their smooth inner lining usually with slightly turbid fluid in its content. Typical calcified cyst produce a gritty sound feeling up on incision [29,30].
