Abstract

Purpose: The aim of this study was to investigate the effect of oxygen plasma treatment on the tensile bond strength of a silicone-based soft liner to a thermocycled denture base.

Methods: 2 10×10×1 mm heat-polymerized acrylic resin blocks for X-ray photoelectron spectroscopy (XPS) analysis were prepared (one served as control, and another treated by oxygen plasma for 4 min). 30 (10×10×1 mm) acrylic resin blocks for contact angle measurement and 80 (8×10×30 mm) for tensile test were also prepared and equally divided into five groups: a control group and four experimental groups (exposure to oxygen plasma for 1 min, 2 min, 3 min and 4 min, respectively). All blocks were thermocycled (5-55°C, 5000 cycles) before oxygen plasma treatment. After oxygen plasma treatment, the soft liner was processed between two blocks according to manufacturer’s instructions and polymerized. All specimens were submitted to a tensile test using a universal testing machine and results were statistically analyzed (ANOVA, p<0.05, Tukey’s HSD test).

Results: The XPS analysis showed that the O/C ratio increased from 0.324 for the control group to 0.498 for the 4-min exposure group. With regard to water contact angle, the lowest value was obtained from the 4-min exposure group (37.32°). For the tensile test, the highest tensile bond strength was observed in the 4-min exposure group (1.998 ± 0.110 MPa) and the lowest was in the control group (0.831 ± 0.059 MPa).

Conclusions: Oxygen plasma treatment was efficient in improving the tensile bond strength between silicone-based soft denture liner and thermocycled denture base.

Keywords: Oxygen plasma; Thermocycled denture base; Silicone soft liner; Adhesive strength

Introduction

The loss of natural teeth may result in psychosocial problems and inability for patients to perform functions. These problems can be corrected with the placement of removable dentures. However, some patients are not able to withstand the forces transmitted by denture bases because of sharp alveolar ridge, atrophied ridge, and thin atrophic mucosa. Resilient denture liners are used to cushion the inner surface of removable dentures, helping to evenly distribute mastication forces, preventing trauma of sensitive mucosa, enhancing denture retention by engaging undercuts [1,2]. The use of silicone-based resilient denture liner in mandibular complete dentures resulted to simulate the aging process. In the present study, thermocycling (5-55°C) was used to study the aging process.

The objective of this study was to evaluate the plasma treatment effect on the tensile bond strength between silicone-based soft liner and thermocycled denture base. The null hypothesis of the study was that the plasma treatment would improve the tensile bond strength between silicone-based soft liner and aged denture base, although the aged denture base is frequently used in clinical practice.

Materials and Methods

Materials

The soft denture liner used was a silicone-based material and the denture base material was a heat-cured poly (methyl methacrylate) (PMMA) acrylic resin. Their types, batch numbers and manufacturers are presented in Table 1.

Preparation of specimens

2 blocks (10×10×1 mm) for X-ray photoelectron spectroscopy (XPS) analysis (one served as control, and another treated by oxygen plasma for 4 min) and 30 blocks (10×10×1 mm) for water contact angle measurement were prepared. Blocks for water contact angle measurement were divided into five groups (n=6) according to the different exposure time applied (1 min, 2 min, 3 min and 4 min, respectively).

In order to prepare the resin blocks for tensile test, a mold was made by investing 2 brass dies of 8×10 mm² cross-sectional area and 30 mm length, together with a spacer (3 mm thick), in hard but flexible silicone rubber (Addition silicone duplicating material) [15]. Molten wax was poured in the mold and allowed to cool, harden and subsequently to be invested in dental stone in a dental flask. After the dewaxing procedures, the heat-cured acrylic denture base resin were packed in the mold and polymerized according to the manufacturer’s instructions. After polymerization, the rectangular acrylic resin blocks were removed from the mold and the bonding surfaces were smoothed using 240-grit aluminum oxide paper, cleaned, and dried. In this manner, a total of 80 resin blocks were prepared. Then all the resin blocks underwent 5,000 cycles in distilled water between 5°C and 55°C, with a dwell time of 30 seconds in each bath [16]. Thus, 80 thermocycled resin blocks were obtained and equally divided into five groups: a control group and four experimental groups (exposure to oxygen plasma for 1 min, 2 min, 3 min and 4 min, respectively). Prior to application of the soft liner, the bonding surfaces of the acrylic resin blocks were treated with oxygen plasma for 1 min, 2 min, 3 min, and 4 min, respectively, and the control group received no surface treatment. A hypo-atmospheric pressure glow discharge (HAPGD) plasma treatment system (HPD-2400, Nanjing Suman Electronics Co., Ltd, China) was used to modify the acrylic resin surfaces.

The operational parameters used in this study were: 20 mbar of the chamber pressure, 80 W of power, and the exposure time were fixed at 1 min, 2 min, 3 min and 4 min, respectively. After plasma treatment, adhesive primer (Sofreliner Tough® Primer) was applied to the bonding surfaces of the acrylic resin blocks according to the manufacturer’s instructions. Then, the two acrylic resin blocks were secured back into the silicone mold, and the soft liner was applied to the space created before (8×10×3 mm) and polymerized following the manufacturer’s instructions. After polymerization, the specimen was removed from the mold and trimmed with a sharp blade. In this manner, 40 rectangular specimens were obtained in a sandwich configuration with a centrally located PMMA portion for silicone-based soft liner (Figure 1).

X-ray photoelectron spectroscopy (XPS) analysis

The composition of elements on the surfaces of untreated and 4 min plasma treated resin blocks was investigated by an X-ray photoelectron spectrometer (XPS) (ESCALAB MK-II, VG Scientific Ltd., UK). An Mg Ka radiation was used as an X-ray anode and the pressure inside the main chamber was lower than 5×10⁻⁹ mm Hg.

Water contact angle measurement

Water contact angles of untreated and plasma-treated resin specimens were measured in air with a contact angle goniometer (SL200B, Solon Tech. Co., China). Deionized water (DI) was used as test fluid for all measurements, and was dropped onto the resin surface using a 1 ml syringe. Each measurement was repeated three times and the average was considered as the final contact angle. The results were statistically analyzed using non-parametric analysis (a=0.05) by SPSS version 20.0 (SPSS Inc., Chicago, IL, USA).

Tensile bond strength test

At 48 hour water storage at 37°C, all specimens were subjected to a tensile force at a crosshead speed of 10 mm/min until failure in a universal testing machine (Serise IX, Instron corp, America). For each specimen, the maximum tensile force before failure was recorded. The tensile bond strength values were calculated as the force at debonding divided by the cross-sectional area of the interface. Data analysis was performed by using SPSS software (SPSS version 20.0 software, SPSS Inc., Chicago, IL, USA). Mean tensile bond strength values were compared by one-way ANOVA and multiple comparisons were carried out with the Tukey’s HSD test. A p<0.05 was considered to be statistically significant.

Results

XPS analysis

Significant change occurred in the 4 min exposure group when compared with the control group. The O/C atomic ratio increased from 0.324 for the control group to 0.498 for the 4-min exposure group. The curve-fitted high resolution C1s XPS spectra of the resin surfaces are shown in Figure 2. The high-resolution C1s spectrum can be deconvoluted into three main chemical states, as C-H, C-O, and O=C-O. The significant change occurred in the 4 min exposure group when compared with the control group was that the C-O and O=C-O contents increased greatly.

Water contact angle measurement

The water contact angles of untreated and plasma-treated resin specimens are shown in Table 2. There is a significant difference between control and each of the plasma treated groups (p<0.05). With oxygen plasma treatment, the water contact angle values dropped dramatically. Prior to plasma treatment, the acrylic resin blocks have average contact angle of 59.99° and dropped to 37.32° after 4 min exposure.

Figure 1: Schematic illustration of a specimen for tensile test.
they are similar to the temperature of food and drink ingested and are well tolerated by the oral mucosa without causing any damage to it [22]. Pinto et al. reported that a single thermal cycle was assumed per meal and 5,000 thermal cycles would relate to roughly 5 years of use [18]. Old denture surfaces usually present problems in bonding and finishing due to their low hydrophilicity and low surface energy.

In this study, to increase the bond strength between the soft denture liner and the thermocycled denture base, a surface treatment modality, namely oxygen plasma treatment, was applied to the resin surface. The hypothesis of this study was that the bonding could be increased by the application of oxygen plasma treatment and the results of the study completely support this hypothesis. Through plasma treatment, oxygen-containing polar groups of C-O and O=C-O were effectively introduced onto the thermocycled resin surface due to the highly reactive property of oxygen plasma [23,24]. This was in line with the conclusion drawn by Bicer et al. who demonstrated that polar functional groups were introduced onto the fresh resin surface after plasma treatment [25]. The value of oxygen-containing groups in the present study was higher than that in previous studies [26,27]. The reason was that the applied hypo-atmospheric pressure glow discharge (HAPGD) system provides more stable and homogeneous discharge with higher electron density when compared with the low pressure glow discharge system.

The presence of oxygen-containing groups improved the surface hydrophilicity of the plasma-treated resin surface as shown by the decrease in water contact angle [23]. It has been concluded that the smaller the contact angle, the greater the hydrophilicity [28]. Süzer et al. measured the water contact angle on plasma-treated resin surface and yielded values ranging between 48° and 54°, which were significantly lower than those of untreated resins with an average value of 63° [29]. In the present study, a lower value ranging between 37° and 44° was observed which indicated that a higher hydrophilicity was obtained compared with the control group. The improved surface hydrophilicity enhanced the penetration of the silicone-based soft liner into the irregularities on the resin surface and contributed to the increase in the tensile bond strength [23].

Silicone-based soft liners tested in the present study had a satisfactory bond strength to thermocycled denture base resin, which is significantly higher than the values observed in other studies [15,30]. Apart from the chemical oxidation reaction, oxygen plasma also has roughening effect on polymer surface. Masood et al. reported that plasma treatment increased the effective surface area of the resin and leads to a more intimate contact between the plasma-treated resin surface and the applied soft liner [31]. During plasma treatment, two competitive effects, namely oxidation effect and etching effect, take place. For the oxidation effect, the surface of the specimens was functionalized and the tensile bond strength of the specimens was increased. This was attributed to continuous introduction of oxygen-containing groups on the resin surface. For the etching effect, chemical

etching was promoted by free radicals generated in O₂ discharge and physical etching occurred under strong ion bombardment [32]. Bicer et al. reported that, as the treatment time is extended, the etching effect dominates, causing the degradation of the polymer surface and decreasing the tensile bond strength [25]. Apart from the outer chain scissions, long time plasma treatment would also cause the inner chain decreasing the tensile bond strength [25]. Therefore, the duration of the plasma treatment is of importance. To sum up, by the results obtained the hypothesis could be completely accepted, because modifying the thermocycled resin surface by oxygen plasma treatment significantly increased the tensile bond strength of PMMA/silicone specimens. However, although in vitro accelerated aging reproduced the effect and the test conditions may not exactly simulate the clinical situations. Therefore, the clinical suitability of these results should be tested further by in vivo studies.

Conclusions

Within the limitations of this study, the following conclusions can be drawn. The XPS results showed that the O/C ratio increased dramatically and oxygen-containing groups of C-O and O=C-O were introduced on the thermocycled resin surface after plasma treatment. The water contact angles of the plasma treated groups were lower when compared with the control group, which indicated that the hydrophilicity of the resin surface was significantly increased. The oxygen plasma treatment was efficient in improving the tensile bond strength between silicone-based soft liner and thermocycled denture base. The highest bond strength was observed for the 4 min exposure group.
