Abstract

Aim: This study aims to find out the frequency of KDR mutation in colorectal cancer patients and if any correlation exists between KDR mutation and demographical features or with other common and uncommon gene mutations occurring in colon cancer.

Methods: FFPE samples of 112 patients were analyzed using next generation sequencing.

Results: KDR gene was found to be mutated most frequently (19.6%) as compared to other uncommon gene mutations occurring among patients. 21/22 patients had the p.Q472H type of KDR mutation. It was significantly associated with mutations in PTEN (p=0.003), KRAS (p=0.026), APC (p=0.033), EGFR (p=0.036), NOTCH1 (p=0.029) and ERBB4 (p=0.008) mutations. More number of males (22.06%) harbored KDR mutations than the number of females (15.9%). A higher number of KDR mutations in Stage III (31%) as compared to other stages – I-II (19.23%) and IV (7.31%) was reported. KDR mutations were found to be in greater number in patients with lymph node metastasis (27.3%) as compared to liver metastasis (8%). However, a statistically significant association of any clinical parameter was not found.

Conclusion: Our results suggest that although KDR is a rare somatic mutation in CRC, it plays a pivotal role in the development of colon cancer via angiogenesis pathway.

Keywords: Colorectal cancer; KDR; Mutation; Next generation sequencing; Rare mutation

Introduction

According to World Cancer Reports 2014, cancer accounted for 8.2 million deaths in year 2012 where colorectal cancer (CRC) was the third most common cancer in men and the second most common in women worldwide [1]. Also, as per the statistics given by Indian Council of Medical Research, CRC incidence in India is reported to be 4 patients per every hundred thousand people. CRC is a fatal disease caused and affected by various genetic mutations in biological pathways. This has been shown in KEGG (Kyoto Encyclopedia of Genes and Genomes) pathway database, that colorectal cancer is associated with and occurs via various biological pathways like Wnt, MAPK, PI3K, mTOR, VEGF, cAMP, p53 and other signaling pathways. These pathways may affect the processes of angiogenesis, gene repair, apoptosis, proliferation and differentiation.

Although all other pathways are equally crucial in development of CRC, VEGF pathway is mainly associated with angiogenesis and is responsible for its regulation in tumors. VEGF Pathway is followed through different signaling cascades depending on the type of signaling stimulus received by VEGF receptors, and thus leading to proliferation, migration, permeability or survival [2]. Any mutation in the proto-oncogenes involved in these pathways may lead to cancer by

transformation into oncogenes. The VEGF signaling pathway has a key element namely KDR, also known as VEGFR-2 (Vascular Endothelial Growth Factor Receptor-2), stands for Kinase Insert Domain Receptor for VEGF-A. It is known to be a proto-oncogene, thus, affecting tumor angiogenesis. KDR gene is located on chromosome 4 at location 4q12. As per Cancerindex.org and Cancer Genetics Web, KDR gene mutation has been previously reported to be associated with lung and breast cancers. Importantly, KDR gene has been previously shown to play an important role in Cancer development via induction of vascularity, metastasis, apoptosis and proliferation in human colon cancer and breast cancer [3,4].

Thus, it highlights the fact that CRC is well known to be associated with and caused by mutations and epigenetic alterations in certain common as well as rare genes regulating cellular signaling pathways like *KRAS*, *BRAF*, *PIK3CA*, *KDR*, *PTEN*, *VHL*, *SMAD4* and others leading to cell proliferation and metastasis. The association of the disease with commonly occurring genetic mutations like those in *KRAS*, *BRAF* and *PIK3CA* has been shown in various studies [5-7] but less attention has been given to the role and correlation of genetic mutations which occur rarely such as those in *KDR*, *PTEN*, *SMAD4* and others. For such a heterogeneous disease, insights into the role of a rare mutation, in this case – KDR, can open new opportunities for treatment based research with KDR as a novel target. Therefore, in this study, we aim to find out frequency of KDR mutation in patients and if

any correlation exists between KDR and demographical features or between KDR and other genes.

Material and Methods

Patients and samples

This study was initially conducted with 146 patients admitted at Sir Ganga Ram Hospital, New Delhi but after tumor content estimation only samples from 112 CRC patients remained. Clinical features of the patients including gender, age, anatomical site, depth of invasion, tumor size, distant metastasis etc. were recorded. December 2015 was the Follow-up end point of the patients under study.

Formalin fixed paraffin embedded (FFPE) blocks, obtained from Department of Histopathology, with tumor content >30% were used for the study and those rejected were because they were old tissue blocks. Microtome was used for extraction of DNA from five to eight sections of 10 µm each. The DNA was isolated using Qiagen ALL Prep DNA FFPE kit following manufacturer's instructions.

NGS analysis

All isolated dsDNA (double stranded DNA) samples and protein contamination were quantified using Nanodrop and QuBit respectively. The DNA samples with 260/280 ratio between 1.7-2.0 were selected for the study. For further qualification, IlluminaInfinium Assay was performed and only those samples having delCT value less than or equal to 2 were chosen. Sequencing library was created using 200-300 ng of dsDNA added to True Seq Amplicon Cancer Panel (Cat. No. FC-130-1008, Illumina) containing a 48 gene panel. Cancer Panel involved 212 amplicons of length 170-190bp which targeted hot spot mutations in 48 cancer related genes. DNA library was denatured, diluted and processed according to Illumina Protocol. MiSeq Reagent Kit V2 (Cat. No. MS-102-2002, Illumina) and MiSeq Reporter (V2.6.2, Illumina) were used to run samples, generate trimmed FASTQ files and align reads against whole genome build hg19.

Strand NGS V2.1.6 was used for further analysis and filtering of reads. The sequencing depth was 200x and target coverage was 5000x. Filtering out of read was done on the basis of failed vendor QC, average quality less than 20, alignment score below 90 and those with ambiguous characters. For detection of variants at locations in target regions covered by a minimum of 10 reads with at least 2 variant reads and variants with a decibel score of at least 50, Strand NGS variant caller was used. Substitution variants with StrandBias greater than 100% and InDel variants in homopolymer stretches greater than 4 with supporting reads of less than 10% were filtered out. 'SNP Effect Analysis' functionality in Strand NGS was used for analyzing the effect on protein and final variants were annotated using COSMIC (Catalogue of Somatic Mutations in Cancer) database.

Statistical analysis

SPSS 17.0 software was used for the analysis of data. Analysis was performed on two main categories of data; comparison of different clinical characteristics with mutations and co-existence of two or more genes together. Pearson's Chi Square test, Chi-square test or Fischer test of association were used to determine the relation between the above mentioned groups. P value of less than 0.05 was considered to be statistically significant.

Results

In the current study, 112 CRC patient samples were analyzed for mutations occurring commonly and uncommonly in 48 genes. The total number of patients characterized according to their demographical characters is given in Table 1. We calculated the per capita statistics of each clinical parameter for all patients having KDR mutation. It is noteworthy that more number of males (22.06%) harbored KDR mutations than the number of females (15.9%). KDR mutation might be associated with people with age >60 as these people were found to have higher number of KDR mutations (23.07%) as compared to those with age ≤ 60 (19.2%). KDR mutation was found to occur more frequently in Rectum (25%) than in Colon (18.5%).

Clinical Parameters	Total no. of patients (n=112)	No. of patients with KDR mutation	(%)
Sex			
M	68	15	22.06%
F	44	7	15.91%
Age			
≤60	73	14	19.18%
>60	39	9	23.07%
Anatomical site			
Colon	92	17	18.48%
Rectum	20	5	25.00%
Location			
Right	46	13	28.30%
Left	46	8	17.40%
Stage			
I-II	26	5	19.23%
III	45	14	31.11%
IV	41	3	7.31%
Depth of invasion			
T2	8	3	37.50%
T3	75	14	18.67%
T4	79	5	6.33%
Metastasis	--	22	--
Liver	25	2	8.00%
Lymph node	22	6	27.30%
No. of Nodes			
N0 (0)	34	5	14.70%
N1 (1-3)	41	6	14.60%
N2 (>3)	37	11	29.30%

Size of Tumor			
<5 cm	35	13	37.10%
≥ 5 cm	77	9	11.70%

Table 1: Clinical characteristics of 112 colorectal cancer patients.

The right side of colon might be linked to KDR mutations due to occurrence of higher frequency of KDR mutations in Right side

(28.3%) while the left side only contained 17.4% mutations. Our study reports higher number of KDR mutations in Stage III (31%) as compared to other stages I and II (19.23%) and IV (7.31%). The T2 stage of depth of invasion with KDR mutation accounts for 37.5% of total patients with T2 stage. KDR mutations were found to be in greater number in patients with lymph node metastasis (27.3%) as compared to liver metastasis (8%).

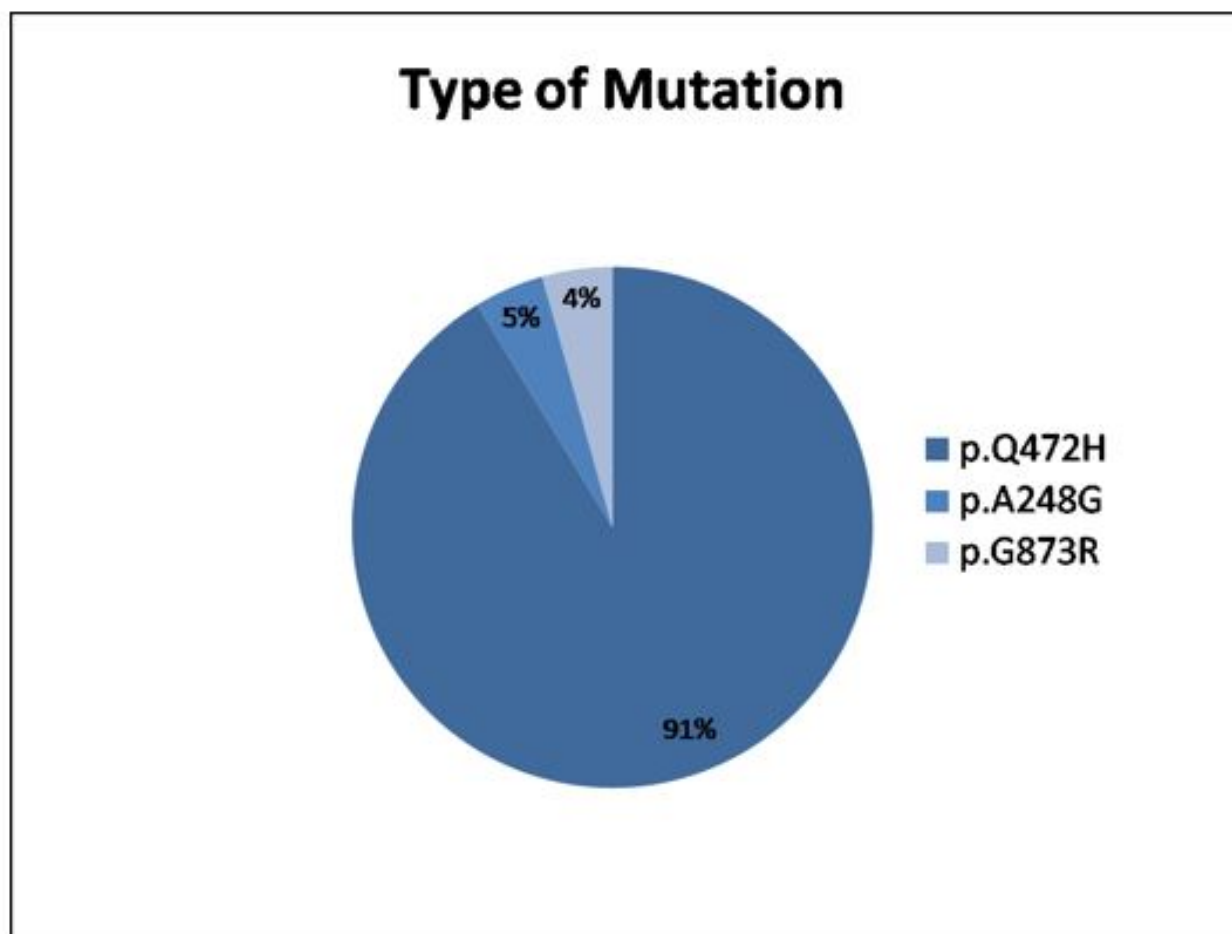

Figure 1: Distribution of type of KDR mutations.

However, our study does not report any statistically significant association of KDR mutation with clinical parameters. In our knowledge, this is the first study targeting at KDR gene mutation in colon cancer using NGS. Out of the mutations in these 48 genes, mutation in KDR was found to be present in 19.6% patients. This is a comparatively high frequency with respect to rarely occurring mutations in other genes. KDR gene was found to contain three types of substitution mutations p.Q472H, p.A248G and p.G873R. The distribution of these mutations among patients is given in Figure 1. 21 patients out of 22 had p.Q472H out of which one had two mutations

including p.Q472H and p.A248G. 1 out of 22 patients was reported to have p.G873R type of mutation.

Upon correlation analysis of the 48 genes, we found significant correlation of KDR with six other genes: KRAS (p=0.026), APC (p=0.033), PTEN (p=0.003), ERBB4 (p=0.008), EGFR (p=0.036), and NOTCH1 (p=0.029) where KRAS, APC, PTEN, ERBB4, EGFR and NOTCH1 occurred in common with 12, 11, 10, 4, 3 and 2 out of 22 patients having KDR mutations respectively. Figure 2 shows the distribution of mutations among patients.

Figure 2: Co-existence of other gene mutations in patients with KDR mutation.

Also, 12 cases of TP53 mutations occurred in coexistence with KDR mutations but the correlation was not of clinical significance. Other genes of the panel did not occur in coexistence with KDR in even a

single patient. Figure 3 shows significantly associated double mutations with KDR.

Figure 3: Significantly associated double mutations with KDR. X-axis represents number of patients with double mutations; Y-axis represents double mutations.

Discussion

Colorectal cancer is widely known to be associated with genetic mutations. These genetic mutations usually contribute to one or the other biological pathway involved in carcinogenesis. Pathways involved in development of CRC majorly include Wnt, MAPK, PI3K, mTOR, VEGF, cAMP, p53 and others (KEGG Pathway Database). But out of all these pathways, VEGF pathway plays a major role in development and progression of CRC by the process of angiogenesis. Vascular Endothelial Growth Factor Receptor (VEGFR), also known as KDR (Kinase Domain Receptor) is a protein involved in functioning of VEGF pathway. Mitogens like VEGF-A bind to KDR and signal cell proliferation and angiogenesis.

Thus, mutations in KDR have been previously found to play a role in increasing cell proliferation and angiogenesis. This brings forth the significance of studies conducted to find association between mutations in KDR and clinicopathological parameters as clinically significant results would help open avenues for new drug formulations. In the light of this, activating mutations in KDR gene have been found to be associated with increased KDR protein expression in human angiosarcoma but it has not been found to be correlated with histological type or grade. Despite no significant correlation with the histology, the same study has been successful in bringing forward the frequency of KDR mutation among the patients under study. A 10% mutation frequency of KDR gene has been reported [8]. Another study reported a frequency of 38/123 patients (30.9%) with mutation in KDR gene in Malignant Pleural Mesothelioma [9]. It is noteworthy to mention here that, a study on non-small cell lung cancer reported high Q472H type of KDR mutation number in 33.3% patients [10] and in

another study, it has been suggested to play a role of proto-oncogene in Lung Adeno-carcinoma [11]. Therefore, a high frequency (19.6%) of KDR mutation among the patients in our study may also indicate its role in developing cancer. Interestingly, our study also reports high occurrence of p.Q472H (21 out of 22 patients) type of mutation which highlights the role of p.Q472H mutation in the KDR gene. This is also substantiated by the study in which p.Q472H has been found to be mutated in large intestine carcinomas [12].

Mutation in KDR gene was found to be higher in Lymph node metastasis as compared to liver metastasis in our study. This supports the study in which expression of VEGF-C, (which upon proteolytic processing binds to VEGFR-2 (KDR)), was significantly associated with lymph node metastasis in gastric carcinoma [13]. But on the other hand, this result is also in contrast to a previous study in which 27% cases with KDR mutations were associated with Colorectal Liver metastasis [12]. This difference might be present due to the small patient population size in our study. KDR gene has been associated with VEGF signaling pathway which is also linked with PI3KCA and PTEN proteins. Our study reports a significant correlation between KDR and PTEN gene mutations which suggests their associated role in development of colon cancer. However, this is in contrast to one study conducted in Small cell lung cancer patients in which PI3K/AKT/mTOR pathway status did not correlate with KDR gene [14]. This difference might be present due to different cancer groups and the small number of patients studied. Furthermore, in a recently reported case study [15], KDR mutation, KRAS mutation and APC mutation were found together in a patient of colon cancer although no clinical significance was reported for their correlation. This case study collectively with our results indicates that KRAS and KDR mutation

can together play a role in proliferation of tumor cells when VEGF signaling pathway proceeds via MAPK signaling route. Not only this, APC and KDR mutations have been independently reported to play a role in tumorigenesis of gastrointestinal cancer and colon cancer but no previous reports of correlation between APC and KDR were found [16-18]. Also, our study suggests a significant correlation between NOTCH1 and KDR (VEGFR2) but we found no literature supporting the same. However, NOTCH1 has been associated with VEGFR1 in previous studies [19]. Moreover, a discussion on NOTCH and VEGF signaling proposes a model where NOTCH1 and VEGFR2 may play symbiotic roles in angiogenesis [20]. This indicates that there might also be an association of NOTCH1 and VEGFR2 in combined development towards angiogenesis which strengthens our results. Interestingly, KDR (VEGFR2) and EGFR have been identified as potential targets for many anti-cancer therapies [21-23] but no studies could be found showing direct correlation between KDR and EGFR. The combined therapeutic targeting to treat cancer is also suggestive of their significant association in regulating cancer pathways which can be seen in our results which shows a significant correlation between mutations in EGFR and KDR genes. Not only this, drugs targeting EGFR, ERBB4 and KDR together have also been studied previously [24]. Moreover, EGFR and ERBB4 belong to the same Receptor Tyrosine Kinase family and work in close association. Thus, a correlation between EGFR and KDR mutations may also indicate the possibility of ERBB4 and KDR mutation. But the results need to be validated by performing assays in larger number of patients.

However, high KDR protein expression has been previously reported in many cancer studies projecting its role in tumorigenesis and angiogenesis [8,25,26]. Overall, this can mean that the KDR mutation leads to high expression of KDR protein. In addition, KDR gene mutation has been previously reported to play a therapeutic role using Regorafenib in metastatic colon cancer [14] as well as in Non-small cell lung cancer [27]. On the contrary, it has also been reported to occur as an adverse effect of Ramucirumab therapy [28] and may lead to side effects when used with FGFR inhibitors for treatment. Additionally, COSMIC database suggests its association with Sorafenib. So, mutation in KDR gene is therapeutically important and any association with clinical parameters or pathways can further help in embarking research focused on drugs targeting KDR. Intriguingly, KDR gene as a potential therapeutic target for angiogenesis inhibitor drugs has been reported previously [29-31].

Conclusion

Our results in combination with previous studies suggest a role for KDR in colon cancer also making it a potential therapeutic target for various drugs like Regorafenib and Sorafenib. Thus, the results from our study can be used for employing targeted therapy in patients with KDR mutations. Besides, it might also be associated with one or more clinical parameters which can help prognostic studies. Significant correlations of KDR mutation with other gene mutations – KRAS, APC and PTEN has shown a new possibility for association of signaling pathways in development of tumors and angiogenesis in Colorectal Cancer. Further studies on KDR and other genes' expression and polymorphisms in colorectal cancer using a larger patient cohort are required for the validation of these results.
