Abstract

Introduction: Several studies have investigated the impact of male obesity on the traditional sperm parameters but it is unclear if in the male obesity, accessory glands secretory function may be altered. In this paper the seminal parameters and the biochemical markers of accessory sex glands are related with the Body Mass Index (BMI).

Material and methods: 1148 patients attending a Fertility Center with subfertility were included in the study. Weight and height were recorded to calculate BMI in each patient. Semen parameters and markers of male accessory glands were measured. Pearson's correlation coefficient has been performed, p-values below 0.01 were considered statistically significant.

Results: In HOS tests a reduction was observed in I and II-III obesity groups, sperm /ejaculate number, seminal volume and citric acid decrease were correlated inversely with the body mass index. Seminal fructose levels tend to increase in proportion to body mass. The correlation analysis in all the individuals indicates a trend for increase in BMI over time.

Conclusion: Obesity has a negative impact on sperm quality and prostatic function, although sperm parameters changes are more evident in men with morbid obesity. Oxidative stress, hormonal and metabolic changes increase as adiposity progresses in an individual, so we may expect infertility, prostate pathologies could be avoided if hyperadiposity in infertile men is controlled opportunely.

Keywords: Male accessory glands; Fructose; Citric acid; Neutral alpha -glucosidase, Obesity

Introduction

The impact of body weight on reproductive health has been more studied in women than in men. Obesity can be conditioned by lifestyle and also has been considered a cause of infertility. Obesity in women can also increase risk of miscarriages and impair the outcomes of assisted reproductive technologies and pregnancy. These adverse effects are specifically evident in polycystic ovary syndrome. In men, obesity is associated with low testosterone levels. In massively obese individuals, reduced spermatogenesis may favour infertility. Moreover, the frequency of erectile dysfunction increases with increasing body mass index [1]. Changes in lifestyle in obese men have been associated with body weight reduction and improved seminal parameters although it is difficult to determine whether seminal quality depends directly on the value of body mass or lifestyle changes [2]. The body mass index (BMI) is a simple and commonly used parameter for classifying various degrees of adiposity. It is derived from the weight of the individual in kilograms divided by the square of the height in meters (kg/ m²). By the current World Health Organisation (WHO) criteria, a BMI <18.5 kg/ m² is considered underweight, 18.5-24.9 kg/ m² ideal weight and 25-29.9 kg/ m² overweight or pre-obese. The obese category is sub-divided into classes I (30-34.9 kg/ m²), II (35-39.9

kg/ m²) and III (≥ 40 kg/ m²), the last two are considered morbid obesity [3].

The prevalence of obesity has risen steadily for the past 35 years and presently affects more than a third of the US population. Obesity alters the hypothalamic-pituitary-gonadal axis both centrally and peripherally, resulting in hypogonadotropic, hyperestrogenic hypogonadism. Adipose tissue-derived factors, like leptin and adipokines, regulate testosterone production and inflammation, respectively. Increased systemic inflammation results in increased reactive oxygen species and increased testicular temperature and inactivity of obese men impairs spermatogenesis [4]. There have been a number of studies on the impact of male obesity on the traditional sperm parameters, but there are many contradicting reports with regard to decrease in sperm concentration, sperm motility and normal forms. And it is currently unclear whether male obesity has an impact on sperm parameters [5].

The problem of obesity triggers several diseases such as diabetes, cardiovascular disease, fatty liver and cancer where oxidative stress is implicated in different physiopathological ways [6]. In obese men the effect of leptin on growth of prostate cancer cells is different according to the androgen sensitivity of the evaluated cells. It's possible that major mitogenic signal transduction pathways, such as, a mitogen-activated protein kinase (MAPK) pathway are involved in leptin exerting its mitogenic effects in these cell lines. Activation of mitogenic

signal transduction pathways by leptin could potentially serve as a target for future therapies of advanced stages of cancer of prostate [7], while in overweight men, other prostatic changes have been observed: increased size, calcifications, lack of echographic homogeneity and high arterial systolic blood pressure. In men with overweight, alterations in seminal vesicles and the epididymis functions, these have not been found [8]. Studies suggest that overweight or obesity can alter the structure and function of accessory glands, so that assessment of chemical markers of accessory glands could be important indicators of these alterations. Male accessory glands secrete several factors which can be measured to assess their function. In particular, citric acid, zinc, glutamyl transpeptidase and acid phosphatase may be used to evaluate prostatic function. Fructose and prostaglandins may be used to evaluate the secretory capacity of the seminal vesicles, free L-carnitine, glycerophosphocholine and neutral glucosidase may be used to evaluate the function of the epididymis [9]. The biomarkers fructose and neutral alpha-glucosidase were useful for to evaluate the impact of some microorganisms on male accessory glands. Some bacteria do not alter sperm density, motility or normal forms, but alter the epithelia of the seminal vesicles and the epididymis, reducing the values of their markers fructose and neutral alpha-glucosidase respectively, and altering other more specific parameters of sperm functionality. It is suggested to incorporate these markers into the study of infertile man [10]. In this paper the seminal parameters and the biochemical markers of accessory sex glands with the Body Mass Index in men attending a Fertility Center are related.

Materials and Methods

Patients

Every one of the analyses was performed after obtaining institutional board approval and each one of the patients gave their express consent. The study was carried out according to the guidelines established by the Helsinki Declaration for human research and outlined in the Code of Bioethics and Biosafety FONACIT [11]. A

clinical cross-sectional analysis was conducted in patients for infertility evaluation at a diagnostic center CEDIEG (Dr. Giovanni Vivas-Acevedo Diagnostic Center for Infertility and Gynecological Diseases), Universidad de Los Andes, Mérida, Venezuela, from January 2010 to April 2017.

A total of 1148 patients with sub-fertility were included in the study. Prior to the seminal evaluation, the information necessary for the pre-analysis including weight and height was recorded to calculate BMI. The patients' height and weight were measured in the same laboratory on the same day that their semen sample was obtained and processed. The patients were included in three groups: normal, pre-obesity, obesity (class I) and morbid obesity (classes II-III) in recognition of the fact that management options for dealing with obesity differ above a BMI of 35.

Semen analysis

Semen samples were collected by masturbation after 2 to 7 days of ejaculatory abstinence. After semen liquefaction, seminal analysis and measuring were performed according to WHO 2010 criteria. Neutral-glucosidase activity and fructose levels were used to evaluate the epididymis and seminal vesicles function respectively [12]. Citric acid was determined by colorimetric reaction following the guidelines of citric acid according to Lozano-Hernández and Vivas [10], the concentration was expressed in mmol/ejaculate as an indicator of prostatic function [13].

Statistical analysis

Statistical analysis has been performed using SPSS 10.0 statistical software for Windows (SPSS, Chicago, IL, USA). Basic descriptive statistics (mean \pm SD) were calculated allotted to the following patients groups: normal, overweight, obesity (class I) and morbid obesity (classes II and III). Pearson's correlation coefficient was calculated and p-values below 0.01 were considered statistically significant.

Total patients	Patient characteristics	N° Patients	Percentage (%)
Patients excluded	Genito-urinary problems*	62	4.0
	Azoospermy	21	1.4
	Post- surgery consult	13	0.9
	BMI less than 18.5	9	0.6
	Incomplete form information	17	1.1
	Patients that presented varicocele	259	16.9
Patients included	Patients that consulted for infertility	1148	75.1
Total		1529	100%

BMI: body mass index. *Genito-urinary problems as infections, prostatitis, hydrocele, pain, torsion, bleeding, inflammation.

Table 1: Male men attending an infertility clinic were invited to participate in an ongoing study of relationship of BMI and seminal parameters. Summary of the patients excluded and included in the study.

Results

Initially, 1529 men were enrolled, of whom 1148 were selected and 381 were excluded because they had seminal infections, prostatitis, hydrocele, testicular torsion, hemospermia, varicocele, azoospermia, genital tract phlogiston, BMI <18.5 kg/ m² and post-surgery. Male men attending an infertility clinic at the CEDIEG were invited to participate in an ongoing study concerning the relationship of BMI and seminal parameters. Table 1 shows a summary of the patients excluded and included in the study.

The results highlight the high frequency of pre-obesity/obesity (42.5%) in individuals cared for in the conjugal infertility consultations. This frequency is higher than China (33.8%) and lower than U.S. rates (65.5%) [14,15]. It can be observed that in BMI values are higher in older men (p<0.01). The samples of men with obesity II-III had lower seminal volume (p<0.001), lower sperm/ejaculate concentration (p<0.01), lower HOST (p<0.01), higher levels of fructose (p<0.01) and lower levels of citric acid (p<0.001) in seminal plasma with respect to other groups.

Patients/Semen quality parameters	Body mass index (kg/m ²)			
	Normal 18.5-24.9	Pre-obese 25-29.9	Obese I 30-34.9	Obese II-III ≥ 35
N° of patients (%)	270 (23.5)	489 (42.6)	280 (24.4)	109 (9.5)
Age (years)	31.9 ± 8.9	34.4 ± 7.9 ¹	34.6 ± 8.0 ²	35.8 ± 8.7 ²
Semen volume (mL)	3.2 ± 1.6	3.5 ± 1.6	3.3 ± 1.6	2.9 ± 1.4 ³
Spermatozoa (x10 ⁶ /ejaculate)	295 ± 232	290 ± 255	284 ± 260	238 ± 211 ^{1,3,5}
Motility (%)	34.0 ± 22.0	34.0 ± 22.7	31.2 ± 21.4	33.3 ± 22.3
Normal morphology (%)	7.9 ± 3.6	7.9 ± 3.5	7.4 ± 3.6	7.6 ± 3.7
HOST (%)	57.6 ± 19.0	59.4 ± 18.5	54.7 ± 20.1 ¹	55.5 ± 19.5 ¹
PMN (mL)	0.6 ± 1.2	0.8 ± 2.5	0.8 ± 1.9	0.8 ± 1.4
Fructose (µmol/ejaculate)	47.6 ± 41.3	51.1 ± 49.0	50.0 ± 39.3	55.5 ± 29.2 ¹
Citric acid (mmol/ejaculate)	99.2 ± 79.7	105.7 ± 80.8	111.1 ± 85.3	85.8 ± 36.2 ^{2,3,5}
Neutral alpha glucosidase (mU/ejaculate)	23.3 ± 13.5	21.9 ± 13.5	21.4 ± 12.2	19.8 ± 14.1

Values are expressed as mean ± SD. Other groups compared with respect to Normal group 1: p<0.01, 2: p<0.001; Pre-obese group 3: p<0.01; 4: p<0.001 and Obese I group 5: p<0.01; 6: p<0.001. PMN: polymorphonuclear granulocyte neutrophils. HOST: hypo-osmotic swelling test.

Table 2: Semen quality parameters grouped according body mass index levels.

Markers of male accessory gland changes are observed mainly in the II-III obesity group (Table 2), but the correlation analysis in all the individuals indicates that there is a subtle tendency for decline in sperm/ejaculate number, seminal volume and citric acid as the body mass index increases, unlike the value of seminal fructose that tends to increase when this index increases (Table 3).

Discussion

Increase in body mass was related to age in this study group. Sperm parameters observed are consistent with some findings that conclude that up to the degree of obesity I there is no direct relationship between BMI and the main sperm characteristics [5].

These results are consistent with the review by Savini et al. (2012), they said that there are many contradicting reports with regard to sperm motility, morphology (normal forms), and it is currently unclear if male obesity has an impact on these parameters [6]. Only HOST was reduced in subjects with obesity I. HOST values have been inversely associated with levels of reactive oxygen species (ROS) in the male genital tract, since this alteration has been determined in the semen of fertile subjects with obesity [16]. Seminal volume and spermatozoa/ejaculate were significantly reduced in men with obesity II-III. In this

group citric acid levels were lowest; this fact allows presuming an association between the citrate anion and chronic oxidative stress. Citric acid has been assigned a restorative role in other tissues damaged by environmental factors, acting as a possible anti-inflammatory and generating the synthesis of glycosaminoglycans [17].

Studies in prostate cancer in obese men have been complicated by the fact that obesity is not only associated with high adiposity, but also with hormonal disorder that compromises testosterone, estrogen, insulin, insulin-like growth factor (IGF)-1, and leptin, which have been linked to prostate cancer.

In vitro studies have demonstrated the mitogenic action of leptin in certain organs. Several isoforms of the leptin receptor have been reported in human tissues including the prostate and testes [18,19]. In this study, no diagnosis or follow-up of prostate cancer was performed as Canacci et al. [20], they studied the chemicals products in the male accessory glands and related them to the Gleason score [20]. Values of citric acid and other prostate products should be evaluated in later studies, especially in the more advanced stages of obesity.

Fructose levels were higher in II-III obesity, although in this study these patients were not categorized as diabetics, the relationship

between diabetes mellitus and obesity ratio in infertile men increases proportionally [21].

Patients/Semen quality parameters	BMI	
	R	p value
Age (years)	0.213	0.001
Semen Volume (mL)	-0.137	0.01
Spermatozoa (x106/ejaculate)	-0.158	0.01
Motility (%)	-0.035	Ns
Normal morphology (%)	-0.079	Ns
HOST (%)	-0.065	Ns
PMN (mL)	0.036	Ns
Fructose (µmol/ejaculate)	0.149	0.01
Citric acid (mmol/ejaculate)	-0.279	0.001
Neutral alpha glucosidase (mUI/ejaculate)	-0.035	Ns

Data was evaluated by Pearson correlation test; BMI: Body mass index; Ns: No significant.

Table 3: Correlations between BMI and seminal parameters.

In seminal plasma of overweight and obese men adiponectin, progranulin and alpha-glucosidase levels are lower and fructose levels are higher than in men with normal weight. Fructose is a carbohydrate transported into sperm and is one of its main energy sources. Whether the high fructose levels in seminal plasma of obese males can explain the changes to sperm mitochondrial function remains to be determined [22].

Conclusions

The results indicate that obesity in a progressive and imperceptible way affects sperm and prostatic functions, although classic sperm parameters are mostly unchanged; oxidative stress, hormonal and metabolic changes are more severe as adiposity increases, so that infertility and prostate pathologies could be improved if hyperadiposity in infertile men is avoided opportunely.

Acknowledgments

We thank Mr. Héctor Picón for his technical work, Doctor Pedro Fernández, Doctor Henry Nava and Doctor Rubén Gallo for the clinical evaluation of the patients referred to the laboratory.
