Abstract

Background: The management of distal tibial fractures can be challenging because of scarcity of soft tissues, their subcutaneous nature and poor vascularity. Consequently, operative treatment can lead to complications. The surgical treatment of fractures has evolved a great deal since the development of the original "open reduction and internal fixation" technique by the AO group. A mechanically stable fracture-bridging osteosynthesis can be obtained without significant dissection and surgical trauma to the bone and surrounding soft tissues by minimally invasive percutaneous plate osteosynthesis (MIPPO). This technique utilizes indirect reduction and internal fixation with locking compression plates. Our aim was to observe the outcome of the distal tibial fracture fixation (extra-articular and intra-articular) with locking compression plate (LCP) using MIPPO technique.

Material and Methods: 26 consecutive patients were prospectively underwent minimally invasive percutaneous plate osteosynthesis for distal tibial fractures between January 2010 and December 2011. Patients were aged between 20 to 65 years with seventeen males and nine females. Both open and closed AO types 43A, 43B and 43C fractures were included. Patients were managed with LCP using MIPPO technique. Postoperative regimen consisted of knee and ankle bending exercises starting on 1st postoperative day. Non weight bearing ambulation started on 3rd post-operative day, progressing to partial weight bearing at 6 to 8 weeks. Full weight bearing ambulation was allowed after clinico radiological union at 12 to 14 weeks.

Observation and Results: RTA was the commonest cause of injury. All fractures healed with good functional outcome. Mean union time was 4.5 months (range 3.5–8 months). Mean follow-up was 14.3 months. For all fractures acceptable active range of ankle movement was achieved. Mean AOFAS score was 88. There were 2 cases of superficial infection, treated successfully with antibiotics. No deep infection, wound dehiscence and hardware failure was noted.

Conclusion: MIPPO is a well-documented technique that offers biological advantages and appears to be a reasonable treatment option for complex unstable distal tibial or pilon fractures that are not suited for intramedullary nailing. The literature is full of studies from developed nations, but studies from developing nations are lacking. Nevertheless small numbers of patients were involved in our study to draw any definitive conclusions, but our encouraging results will motivate the trauma surgeons from the developing nations to use MIPPO technique in managing distal tibial fractures, in an endeavor to reduce morbidity and associated complications, especially of the soft tissues.

Keywords: MIPPO technique; RTA; Fracture-bridging osteosynthesis; Locking compression plate; Indirect reduction

Introduction

Fractures of the distal tibial metaphysis with or without intra-articular extension can present a management challenge because of their inherent instability, scarcity of soft tissues, subcutaneous nature and poor vascularity of bone. Treatment modality is dictated by the fracture displacement, comminution, intra-articular extension and injury to the soft-tissue envelope [1]. The surgical treatment of fractures has evolved a great deal since the development of the original "open reduction and internal fixation" technique by the AO group, even though high rates of complications have been reported in literature with conventional methods [2-6]. Although intramedullary nailing minimizes surgical trauma to already traumatized soft tissues, but generally not considered suitable for distal tibial fractures because of lack of biomechanical stability of fixation and subsequent risk of malunion. Conventional plating results in extensive soft tissue dissection and periosteal injury, further compromising the blood supply to already traumatized soft tissues. External fixators are effective in managing compound fractures and fractures associated with extensive soft-tissue injury, but are also not free of complications, and are associated with a high incidence of pin tract infection, loosening and malunion [7]. A mechanically stable fracture-bridging osteosynthesis can be obtained without significant dissection and surgical trauma to the bone and surrounding soft tissues by minimally invasive percutaneous plate osteosynthesis (MIPPO) [8]. This technique utilizes indirect reduction and internal fixation with locking compression plates. The plate is tunneled subcutaneously, but extra periostially, through limited skin incisions placed at the proximal and distal ends of the plate, bypassing the fracture site and then making a stable construct by judicious use of compression and locking screws. This technique aims to preserve bone biology and minimizes surgical trauma to already traumatized soft tissues. MIPPO with LCP offers biological advantages over conventional plating techniques in terms of low surgical trauma, preservation of the...
blood supply, lesser evacuation of osteogenic fracture hematoma and stable construct [8-10]. Our aim was to observe the results of the distal tibial fracture fixation with locking compression plate using MIPPO technique in terms of clinical and functional outcome.

**Material and Methods**

We prospectively followed the 26 consecutive patients who underwent minimally invasive percutaneous plate osteosynthesis using LCP for distal tibial fractures between January 2010 and December 2011. At start of study, permission was taken from hospital ethical committee and informed consent was obtained from all patients. Patients were aged between 20 to 65 years (mean age of 43 years) with seventeen males and nine females. We included all patients presenting to our outpatient or emergency department with high energy distal tibial fractures with or without intra-articular extension. All closed injuries, compound grade I and grade II fractures were included in the study. Compound grade III fractures were excluded from the study because of the presence of severe soft tissue injury, periosteal stripping and loss of fracture hematoma, which may lead to confounding. There were 19 closed and 7 open fractures (compound grade I=5 and grade II=2). Antero-posterior and lateral radiographs of ankle including leg were used to determine the fracture personality (displacement, comminution, intra-articular extension) and then classifying the fracture accordingly (Figure 1). Fractures were classified according to the AO comprehensive classification system [11]. There were eighteen 43A, six 43B and two 43C fractures. Open fractures were classified according to the Gustilo and Anderson classification system [12]. Fifteen patients were involved in road traffic accidents and eleven had a fall from height. All of the patients had an associated fibular fracture. On presentation all open fractures were managed with debridement and primary fixation, while closed injuries were managed initially with below knee plaster slab and elevation of the fractured extremity. The definitive fixation with locking compression plates using MIPPO technique was undertaken after subsidence of soft tissue trauma (Figure 2). Postoperative plaster cast immobilization was not used routinely. Postoperative regimen consisted of knee and ankle bending exercises starting on 1st post-operative day. Non weight bearing ambulation started on 3rd post-operative day, progressing to partial weight bearing at 6 to 8 weeks. Full weight bearing ambulation was allowed after clinical and radiological union of lower third of fibula.

The final outcome was evaluated at mean of 14.3 months. Clinical union was defined as single stance, painless full weight-bearing on the healed fractured extremity (Figure 3). Radiological union was defined as evidence of bridging callus in both the orthogonal views (Figure 4). Delayed union was labeled when patient does not met the above said criteria of union at nine months. Soft tissue outcome was evaluated from history of infection (superficial or deep), wound dehiscence, hardware impingement and necessity for hardware removal. American Orthopaedic Foot and Ankle Score (AOFAS), time back to work and change of work in relation to the injury were used to assess the functional outcome.

**Operative Technique**

The patient was positioned supine on operation table, with a thigh tourniquet. Intravenous antibiotics were given, before inflating tourniquet. Before proceeding to percutaneous plating, the fibular fracture was fixed first using a one-third tubular or recon plate, which helped in maintaining the length, alignment and indirect reduction of the tibial fracture (Figures 5a and 5b). In all cases fibular fixation was done. Following lateral malleolar fixation the integrity of syndesmosis was checked by pulling the distal fibula. After conventional plating of lateral malleolus, distal tibial LCP was tunneled sub-cutaneously, through limited skin incisions avoiding injury to the saphenous nerve and vein (Figure 5c). Plate was temporarily fixed using K-wires through the especially designed holes on the distal and proximal ends of the plate. Preliminary reduction and position of plate was checked under image intensifier. Interfragmentary compression was accomplished in selected cases with cortical screws placed through the plate (Figure 5d). Following inter fragmentary compression a mechanically stable construct was made by use of locking screws. All through the fixation care was taken to prevent posterior sagging of the tibia at the fracture site. Wound closure was done in layers without a suction drain. Following operation compression bandage was given, and limb was elevated. No splintage was used postoperatively.

**Observation and Results**

All patients were followed in outpatient department for clinical and radiological outcome. The mean number of days between admission and definitive fracture fixation was five days (range 0–9 days). Mean duration of operation was 95 min (range 80–125). The fibula was fixed...
in all cases. Bone grafting was not done in any of our case. Mean follow-up was 14.3 months (9–23 months). Mean union time was 4.5 months (range 3.5–8 months). Out of the 19 closed fractures, 15 fractures went to clinico radiological union within six months of operation, while rest of the four fractures took more than six months. Out of the 7 open fractures, six fractures healed within six months, while one patient with compound grade II fracture required 10 months for healing. There were two cases of superficial infection in open fracture group, managed successfully with antibiotics. None of the patient developed deep infection or wound dehiscence. All patients achieved functional active range of ankle movements. Mean AOFAS score was 88 at a mean of 14.3 months follow-up. There was no case of hardware failure, but four (14.3%) patients reported plate impingement.

One patient in open fracture group developed delayed union. None of the patient developed non-union. Two patients developed 5 degrees of valgus mal-alignment, no significant recurvatum or pro-curvatum was noted in any of our case. No temporary fixation with an external fixator was done for initial soft tissue management. All patients were back to their pre-injury employment, and out of twenty six, 21 (80.8%) patients were back to work within 6 months of injury, while rest of the patients required more than 6 months.

**Discussion**

The treatment of unstable distal tibial or pilon fractures remains controversial. Management and severity of the soft tissue injury is one of the most important determinants of the prognosis of distal tibial fractures. Complications such as wound dehiscence, infection, and non-union can be seen when soft tissue status is ignored [10]. Conventional methods of distal tibial fracture fixation have been associated with high rates of complications, such as wound infection, mal-union, non-union and hardware failure [2-6]. External fixation and intramedullary nailing techniques, beyond doubt minimize soft-tissue trauma and have been shown to diminish infection but their use is complicated by mal-union, non-union, unsatisfactory reduction of articular surface, and pin tract infection [2-6,13-15].

Open reduction in the distal tibia causes an increased risk of disrupting the blood supply, as shown by Borelli [16]. Hence, conventional plating of distal tibial fractures has been associated with
A solemn decline in the rate of infection, especially deep infection in the MIPPO technique are better than in previously reported ORIF infection was reported with conventional ORIF [22]. Infection rates in management of distal tibial fractures [17-21]. The highest rate of results for MIPPO using closed, indirect reduction and contoured tibial or pilon fractures. The literature is full of studies from developed countries. High rates of infection and soft-tissue complications requiring multiple surgeries.

Preservation of soft-tissue integrity is particularly critical with distal tibial injuries because the antero-medial cortex is subcutaneous, and the remaining soft-tissue envelope is thin. As a result, minimally invasive plating techniques have been developed. LCP using MIPPO causes minimal soft tissue damage. Therefore, it has a biological advantage over ORIF in that it preserves the periosteal blood supply and as a result increases the chance of healing [8,17].

Minimally invasive percutaneous plate osteosynthesis (MIPPO) is a well-documented technique that offers biological advantages and appears to be a reasonable treatment option for complex unstable distal tibial or pilon fractures. The literature is full of studies from developed nations [8,10,16-18], but studies from developing nations are lacking. Akseki et al. [10], Borg et al. [17], Redfern et al. [18] reported good results for MIPPO using closed, indirect reduction and contoured dynamic compression plates for distal tibial fractures [10,17,18].

Infection rates vary between 0 and 50% subsequent to operative management of distal tibial fractures [17-21]. The highest rate of infection was reported with conventional ORIF [22]. Infection rates in the MIPPO technique are better than in previously reported ORIF studies and are comparable to external fixation technique [17,20,21,23-27]. A solemn decline in the rate of infection, especially deep infection has been observed in patients managed with MIPPO technique. None of our patient developed deep infection, however two patient developed superficial infection, which is comparable to the existing literature.

Although, mal-reduction and mal-union has been reported in literature with minimally invasive approaches, but is of less of concern in comparison to intramedullary nailing and external fixator [2]. This is also reflected in our study with only 2 (7.7%) patients having tibial mal-alignment of 5° of valgus and none of the patient developing significant recurvatum or pro-curved post-operatively and at union, which is in conformation with Maffulli et al. [28] and Khoury et al. [29]. This can be further minimized by accurately pre-contouring the plate or using the pre-contoured plates, making a mechanically stable construct by using the technique wisely and fixing associated fibular fracture. However, the clinical impact of fixing associated fibular fractures when stabilizing distal tibial fractures remains indefinite. In our experience, fibular plating is a useful adjunct in the setting of significant metaphyseal comminution in which rotational and sagittal alignment may be difficult to maintain with plate alone. We found that concurrent fibular fixation along with percutaneous plating is helpful in restoring length, alignment and indirect reduction of the tibial fracture in displaced and comminuted fractures.

Mean fracture healing was observed at 4.5 months (3.5-8 months). Our results were comparable to other studies using the MIPPO technique [10,17,28,29]. Comparing the results with other methods of fixation, our results are better in comparison with ORIF and external fixation [2-6,17,23]. However, Hasenboehler et al. [30] reported prolonged healing times with MIPPO technique in simple fracture patterns [30]. One patient in open fracture group developed delayed union. The fracture progressed to successful union at ten month post-operatively.

Distal tibial plating by MIPPO technique provides rigid fixation, which obscures the routine use of plaster immobilization in postoperative period. This in turn allows early active ankle exercises. In our study, mean AOFAS score of 88 was noted at 14.3 months of mean follow-up. Our study also favors that ankle stiffness is not a problem in management of distal tibial fractures with MIPPO technique [17,28,29,31].

In terms of weight bearing, our results are comparable to Maffulli et al. [28], Khoury et al. [29], Bahari et al. [31], Redfern et al. [18] instructed full weight-bearing ambulation following clinical evaluation and the radiological appearance of callus formation [18]. Likewise in our study, non weight bearing ambulation was started on 3rd post-operative day, progressing to partial weight bearing at 6 to 8 weeks (mean 6.2 weeks) and full weight bearing ambulation at 12 to 14 weeks (mean 12.4 weeks) at clinico-radiological evidence of union. Ozkoc and Tandonan RN [32] reported that bone failure can be prevented by using plates in a manner by distributing stresses over a large area [32]. In current study, due care was taken to follow above observation which was reflected in our results also, with no case of bone or implant failure.

As already discussed none of our case had hardware failure, but plate impingement was of significant concern in four (14.3%) cases. None of our patient opted for hardware removal as plate impingement was not interfering with activities of daily living. Similar results were reported by Cheng et al. [33] whereby none of their cases also not opted for plate removal [33]. However a higher percentage of plate impingement was reported by Lau et al. [34] whereby 52% (25/48) of...
distal tibial fracture cases treated by MIPPO had the implants removed due to skin impingement. Plate impingement resulting in skin irritation problems could be related to the thin subcutaneous nature of distal tibia and suboptimal pre-contouring of plates. Furthermore, the residual malreduction also contributes to the impaction of plate and bone contouring. Anterior knee pain is not an issue with MIPPO technique in comparison to intramedullary nailing [2,3].

One of the shortcomings of MIPPO is that it does not allow direct visualization of the fracture site and hence the operating surgeon is reliant on intra-operative fluoroscopy to confirm the reduction, plate insertion, insertion of drill guides and locking screws, thus increasing radiation exposures. To overcome the risk of radiation exposure, Rijal et al. [35] described a technique for minimizing radiation and incision with MIPPO (MRI-MIPPO) [35]. Author has used another plate of same length (plate over plate technique) for locating the locking holes with wires, so that all proximal and distal screws can be inserted with stab incision. In their study, 3–4 image intensifier views were required for completing the entire procedure.

To conclude, treatment of unstable distal tibial or pilon fractures remains challenging and is dictated by the fracture displacement, comminution, intra-articular extension and injury to the soft-tissue envelope. MIPPO is a well-documented technique that offers biological advantages and appears to be a reasonable treatment option for complex unstable distal tibial or pilon fractures that are not suited for intramedullary nailing. The literature is full of studies from developed nations, but studies from developing nations are lacking. Nevertheless small numbers of patients were involved in our study to draw any definitive conclusions, but our encouraging results will motivate the trauma surgeons from the developing nations to use MIPPO technique in managing distal tibial fractures, in an endeavor to reduce morbidity and associated complications, especially of the soft tissues.
