Abstract

Background: In recent years, some observational studies suggested that pramipexole, a non-ergot dopamine agonist (DA) used for the treatment of Parkinson’s disease (PD), may increase the risk of heart failure (HF). However, the limitations inherent in observational studies made it difficult to determine whether the excess of incident HF was related to the drug or to other determinants. Thus, some concerns remained regarding the increased putative HF risk associated with non-ergot DAs as a class or individually.

Method: In our meta-analysis, primary endpoint was the risk of incident HF in patients with PD treated with non-ergot DAs compared to those treated with monotherapy with levodopa. Secondary outcome measures were all-cause mortality and cardiovascular events. For these purposes, only randomized controlled trials (RCTs) were considered, provided that they offered complete outcome data pertaining to the incident HF, all-cause mortality and risk of cardiovascular events. Systematic searches were performed in the databases of PubMed, Embase and ClinicalTrial.gov up to May 2015. The effect size was estimated using the pooled relative risk (RR) of non-ergot DAs versus placebo on incident HF as well as on all-cause mortality or cardiovascular events.

Results: Six out of 27 RCTs reported at least one case of incident HF; therefore, we included them in the RR estimate, whereas 13 RCTs were included in the meta-analysis for mortality rates and 22 RCTs were included to evaluate cardiovascular events. Treatment with non-ergot DAs did not reveal an increase in the risk of incident HF as compared with the placebo group (pooled RR: 0.95, 95% CI: 0.30–2.90; p = 0.893). Similarly, patients treated with non-ergot DAs didn’t show any significant differences compared to controls with regard to all-cause mortality (pooled RR: 0.617, 95% CI: 0.330–1.153; p = 0.13) as well as with regard to cardiovascular events (pooled RR: 1.067, 95% CI: 0.663–1.717; p = 0.780).

Conclusion: The use of non-ergot DAs in PD patients was not associated with an increased risk of incident HF, nor was it shown to increase the overall mortality or the risk of cardiovascular events compared to the PD patients taking monotherapy with levodopa alone. However, larger studies are warranted to confirm the cardiovascular safety of non-ergot DAs for PD management.

Background

Parkinson’s disease (PD) involves alterations of the extrapyramidal nervous system, which regulates posture and voluntary movements, and is characterized by symptoms such as resting tremors, rigidity and akinesia [1]. It is a neurodegenerative disease caused by degenerative and apoptotic injury of the basal ganglia from an unknown cause [2]. The disease itself is not fatal; however, it produces a progressive deterioration in motor function, which can lead to disability and significantly elevated risks of choking, pneumonia, and falling-related injuries, resulting in a marked reduction in life expectancy [1].

The therapy is primarily based on the administration of levodopa associated with inhibitors of its peripheral degradation such as carbidopa or benserazide [3]. Moreover, for many years, dopamine agonists (DAs) have been incorporated into the therapeutic armamentarium of PD [3]. These drugs, which are commonly subdivided into ergot and non-ergot dopaminergic derivatives, activate the dopamine secretion in the central nervous system with various mechanisms, by acting on dopaminergic neurons located in the substantia nigra, in the corpus striatum and in other extrapyramidal structures in the brain. Levodopa is currently the most effective agent used in the treatment of PD and has been the mainstay of therapy in recent decades. DAs are less effective than levodopa as a treatment regimen; however, they are associated with lower risks of dyskinesia and motor fluctuation. This has led to the wide-scale application of DAs in the early stages of PD in order to postpone the use of levodopa, or as an add-on treatment to reduce levodopa dosages [4,5].

Evidence suggests that older, ergot-derived DAs, pergolide and cabergoline, induce thickening and dysfunction of the cardiac valves [6-12]. Thus, more recently developed non-ergot-derived DAs, such as pramipexole, ropinirole or rotigotine, are increasingly being used as replacements for ergot-derived DAs in the management of PD. However, in September 2012, the U.S. FDA released a safety communication [13] related to a possible increase in the risk of heart failure associated with non-ergot DAs as a class or individually.

failure following treatment with pramipexole, i.e. one of the most used non-ergot DAs, based on the pooled data from two phase II and III RCTs submitted by the manufacturer [13]. In these studies, a larger percentage of patients in the pramipexole group were diagnosed with incident heart failure compared to the placebo group; however, the difference did not reach statistical significance [13]. In addition, four case-control studies were undertaken to assess the relationship between ischemic events, heart failure, and the use of ergot and non-ergot DAs; however, the results were inconsistent [14–17]. These observational studies enrolled large numbers of participants for safety evaluations; however, their findings were inherently susceptible to confounding effects propitiated by the severity of PD, comorbidities, unmeasured confounders, confounding by indication, detection bias, and accuracy of heart failure outcome definition [18].

The present study sought to overcome the potential drawbacks associated with observational studies and the inconclusive findings reported in individual trials by conducting a meta-analysis of RCTs related to the use of non-ergot DAs in patients with PD. Our primary focus was on the risk of newly diagnosed heart failure in patients with PD who were treated with non-ergot DAs compared to those who were not; secondary outcomes were all-cause mortality and frequency of cardiovascular events.

Method

This study complied with the preferred reporting items for systematic reviews and meta-analysis (PRISMA) guidelines [19] with a predefined protocol elaborated by the authors.

Data sources and search strategy

We searched the PubMed, Embase and ClinicalTrials.gov databases from inception to May 2015. Full-text terms and Medical Subject Headings terms (MeSH) used for systematic database searching included Parkinson’s disease (PD) and dopamine agonists (DAs) Table 1. The PubMed search strategy through the PubMed filter was the following: “idiopathic Parkinson’s disease” [MeSH Terms] OR “Parkinson’s disease” [All Fields] AND (“piribedil” [All Fields] OR “rotigotine” [All Fields] OR “ropinirole” [All Fields] OR “pramipexole” [All Fields] OR “dopamine agonists” [MeSH Terms] OR “dopamine agonist” [All Fields]). For this database, the search results were further restricted to randomized controlled trials (RCTs). For the databases of ClinicalTrials.gov, search results were restricted to trials with announced results.

Eligibility criteria

The study inclusion criteria were as follows: (a) RCTs; (b) studies on patients diagnosed with PD in any stage; (c) studies involving patients who received non-ergot DAs, alone or in combination with other anti-Parkinsonian treatments as an intervention, versus a placebo as a control; and (d) trials providing data about the occurrence of incident heart failure and/or all-cause mortality and/or cardiovascular events. Trials lasting twenty-four weeks or longer were included to study the long-term effects of non-ergot DAs. We excluded small trials with fewer than ten participants in each arm of the intervention, delay-start or crossover trials that did not provide information concerning adverse events specifically on the drug exposure period, studies published only in protocols, abstracts, and research in languages other than English.

Outcome measures

In this study, the primary outcome was the risk ratio of incident heart failure, i.e., the ratio of the risk of newly diagnosed cases of heart failure among PD patients taking non-ergot DAs (exposed group) to the corresponding risk of incident heart failure found in PD patients free from non-ergot DAs (non-exposed group). The secondary outcomes were adverse cardiovascular events or mortality. From all eligible trials, we retrieved the number of events pertaining to incident heart failure, all-cause mortality and cardiovascular events (regardless of severity) from the listings of adverse events in the original articles. Adverse cardiovascular events were defined as a composite outcome of ischemic heart disease (coronary heart disease, myocardial infarction, acute coronary syndrome, and angina), cerebrovascular disease (stroke and transient ischemic accident), heart failure (including acute cardiac failure and exacerbation of heart insufficiency), valve disorders and arrhythmias/tachycardia (including atrial fibrillation).

Data extraction

All articles identified were screened based on their titles and abstracts (Figure 1). The eligibility of potentially relevant trials was evaluated based on the full-text articles. If trials produced multiple publications, the most recent publication or the publication with the most complete information was included. For each eligible trial, a definite number of relevant characteristics was searched for: (a) trial characteristics (author, publication year, type of treatment, number of subjects included, study location, study duration, PD stage, cardiovascular-specific exclusion criteria); (b) patient characteristics at baseline (mean age, proportion of females) and withdrawal rate; (c) number of PD patients with incident heart failure; (d) number of all-cause deaths; and (e) number of PD patients with cardiovascular events. Two investigators (RDV and CC) independently assessed identified references and extracted relevant characteristics and outcomes from the eligible trials. Discrepancies were resolved by aid and consultation of another independent observer (DM).

Statistical Analysis

In this study, we adopted the intention-to-treat analysis strategy. For the comparison of non-ergot DAs versus a placebo, we estimated the risk of incident heart failure as well as those of mortality from all causes or cardiovascular events, respectively, with the pooled relative risk (RR) and 95% confidence interval (CI). For trials in which multiple groups were administered a single non-ergot DA, the data was summarized into a single overall estimate. In contrast, for trials using more than one non-ergot DA, data was managed as separate trials with the placebo conditions.
group serving as a common reference. Both fixed and random effects models were used to assess the RR of incident heart failure (primary outcome) or of mortality or cardiovascular events associated with the use of non-ergot DAs. Sensitivity analyses were performed to deal with sparse outcome data. Statistical heterogeneity was evaluated using the I² statistic, with a value of 50% or more indicating a substantial level of heterogeneity. To investigate potential publication bias, we visually inspected the contour-enhanced Begg’s funnel plot for any asymmetry. To explore possible effect modifiers pertaining to incident heart failure associated with the use of non-ergot DAs, we performed a stratified analysis on studies that included PD of various stages (early or advanced) or follow-up periods of different lengths (short term: < 24 weeks or long term: ≥ 24 weeks). We also evaluated the risk of individual non-ergot DAs on the occurrence of newly diagnosed heart failure. STATA version 9.0 was used for the analysis, and Review Manager® 5.3 was used for plotting risk of bias graphs. A two-sided α value of 0.05 was defined as statistically significant.

Results

Twenty-seven studies fulfilled the eligibility criteria for at least one of the outcomes provided for by the meta-analysis protocol (incident heart failure assumed as a primary outcome, all-cause mortality and cardiovascular events taken as secondary endpoints) [20–46] (Figure 1). Thus, six trials were deemed eligible for heart failure [24,27,32,35,36,41]
Primary Outcome

The use of non-ergot DAs and incident heart failure

For newly diagnosed heart failure, six out of 27 trials reported at least one case of incident heart failure and were, therefore, included for RR estimation [24,27,32,35,36,41]. Among the 4,560 PD patients treated with non-ergot DAs, only eight cases of heart failure were reported. Among the 2,359 PD patients in the placebo group, only four cases of heart failure were reported. Treatment with non-ergot DAs did not reveal an increase in the risk of heart failure as compared with the placebo group (RR: 0.95, 95% CI: 0.30–2.90) (Figure 2). No significant heterogeneity was observed across the studies for the outcome “incident heart failure”. Due to the small number of trials in each stratum, the stratified analysis was unable to detect effect modifiers or any significant interactions (Figure 5-7) (Table 1).
Secondary Outcomes

The use of non-ergot DAs and overall mortality

For all-cause mortality, 13 out of 27 trials [21,24,27–31,34–36,38,43,46] reported at least one death and were, therefore, included in the RR estimation (Figure 3). A total of 5,686 PD patients were enrolled (mean age of 64 years, 42.7% female). Four of the trials [21,29,34,36], seven of the trials [20,24,28,30–31,38,42], and two of the trials [27,41] included patients in early and advanced stages. The follow-up time ranged from twelve to forty weeks. Six of the trials [20,21,37,38,41,42] were defined as short-term trials (within 24 weeks). There were 20 deaths among the 3,858 patients who received non-ergot DAs and 21 deaths among the 2,447 patients in the placebo group. Regarding the risk of all-cause mortality, patients treated with non-ergot DAs did not show any significant difference compared to controls (random effects RR: 0.617, 95% CI: 0.330–1.153; p = 0.13) (Figure 3). Moreover, the effects of using non-ergot DAs on mortality were consistent across groups of studies with different lengths of follow-up and across individual drugs.

The use of non-ergot DAs and cardiovascular events

For cardiovascular events, 22 out of the 27 trials [20–23,25,26,32,33,35,39,41–46] reported at least one cardiovascular event; thus, they were judged suitable for inclusion in the meta-analysis. Among the 6,734 PD patients, the mean age was 63.8 years and 41.1% were female. Eight trials [21,22,24,28,34,36,39,46] dealt with patients with early PD, seven of the trials [20,24,28,30–31,38,42] recruited patients with advanced PD, and two of the trials [27,41] included patients in early and advanced stages. Sixteen trials [20–23,25,26,32,33,35,39,41–46] were defined as short-term (within 24 weeks) with regard to the duration of follow-up. In the random effects model, patients treated with non-ergot DAs did not show any significant difference with regard to the risk of cardiovascular events compared to patients taking a placebo (random effects RR: 1.067, 95% CI: 0.663–1.717; p = 0.789) (Figure 4).

Discussion

The proportion of PD patients who experience heart failure is higher than among those without PD, probably due to autonomic dysfunction and neurohormonal dysregulation, which have been well demonstrated in PD [47–49]. Thus, careful evaluation regarding cardiovascular safety of anti-Parkinson medications is a crucial issue. Concerns arose from isolated reports that highlighted that non-ergot DAs may precipitate heart failure, judging from the quite worrying information provided in this regard by several case reports [50] and observational case-control studies [14–17]. In particular, three different case-control studies showed that pramipexole increased the risk of heart failure (HF). First, Mokhles et al. found that this increased risk was especially high during the first months of treatment in PD patients over the age of 80 [15]. Renoux et al. [16] also highlighted a higher risk of HF with pramipexole compared to the other DAs used in treating PD and restless legs syndrome. According to these authors [16], in a cohort of 26,814 subjects taking DAs, the incidence rate of HF increased with the current use of a DA; in particular, it was significantly higher for pramipexole and cabergoline, whereas it was not significantly increased by ropinirole. The increased risk for HF associated with pramipexole was, however, not significant, when compared with all DAs taken collectively. Therefore, we can infer that the increased risk
of HF is not a class effect, and the ergoline structure is likely not be implied in this complication, since the deterioration in pump function would occur in both ergot-derived (cabergoline, pergolide) and non-ergot related (pramipexole) DAs. Hsieh and Hsiao [17] studied the risk of DA-related HF among Asian patients. They found an increased, but nonsignificant, risk with pramipexole proportional to the duration of use. In this study, HF was not found in patients with a history of peripheral edema, with the mechanism most likely being different. In addition to a high affinity for the dopamine D2, D3, and D4 receptors, pramipexole is also an alpha-2-adrenergic receptor agonist [51,52]. Thus, it is possible that pramipexole directly activates the α2-adrenergic autoreceptors, thereby reducing adrenergic tone and myocardial contractility. Consequently, in September 2012, the US Food and Drug administration warned of a possible increased risk of heart failure with pramipexole use in PD patients [13]. However, the limitations inherent in observational studies (in particular, detection bias, interference by known or unknown confounding factors, confounding by indication, etc.) make it difficult to determine whether the excess of a given pathologic event, e.g. heart failure is related to the drug or to other determinants. Therefore, no conclusion was reached by the FDA in this regard, and the warning released in September 2012 was not followed by actions aimed at its marketing limitation or by restrictions concerning the drug’s therapeutic indications. Contrary to some [15–17], but not all, observational studies suggesting that several non-ergot Das, such as pramipexole, may increase the risk of heart failure, we did not observe a significant increase in the risk of heart failure associated with non-ergot DAs, as a class or individually, in an RCT setting. This discrepancy may be because observational studies tend to be more vulnerable to confounding by underlying comorbidities and detection bias, i.e. physicians may preferentially prescribe non-ergot DAs to PD patients with poor cardiac function (so-called confounding by indication) and pay more attention to monitoring the symptoms of heart failure. As a result, the users of non-ergot DAs would be more likely to be diagnosed with incident heart failure. Our meta-analysis revealed similar rates of all-cause mortality among PD patients receiving non-ergot DAs compared to those receiving only a placebo (Figure 3). Furthermore, the use of non-ergot DAs was shown not to be associated with an increased risk of cardiovascular events, including myocardial infarction or ischemic stroke (Figure 4). Thus, our results seem to affirm the substantial cardiovascular safety of non-ergot DAs, even among PD patients with a higher prevalence of heart failure and cerebrovascular disease [53,54].

Figure 5: Forest plot of meta-analysis of randomized controlled trials of non-ergot dopamine agonists and the risk of heart failure in Parkinson’s disease patients: stratified by individual drugs.
Implications and inferences of the meta-analysis

Unlike case-control studies, the results obtained in RCTs are less susceptible to residual or unmeasured confounding, e.g. PD severity, comorbidities and a physician’s tendency to use innovative treatments, e.g. non-ergot DAs, especially in patients with a more deteriorated and drug-refractory clinical picture. The limitations of this study primarily reflect the challenges of assessing drug safety in clinical trials. First, only a limited number of trials reported cardiovascular events, which prevented us from conducting further subgroup analyses or meta-regression adjustments to check for the mediation of effects by important characteristics. Second, none of the trials included cardiovascular events as predefined outcomes and these endpoints were not defined uniformly across trials. Therefore, the misclassification of these adverse events is possible. Nonetheless, all of the trials included in this study were double blind, so that any such misclassification is likely to be non-differential, which may bias the results toward the null. Third, some of the studies we included did not provide detailed information related to adverse events, particularly cardiovascular events (possible selective reporting bias). Fourth, we were unable to evaluate confidently the long-term safety of non-ergot DAs due to limitations in the availability...
Comparison with previous findings and implications of findings

In our meta-analysis, the risk of overall mortality in the DAs group was similar to that observed in the placebo group. This finding somewhat conflicts with an earlier systematic review and meta-analysis, which reported an RR of 0.45 (95% CI: 0.21–0.97) when comparing the all-cause mortality in the patients’ group treated with DAs plus levodopa in comparison with those treated with levodopa alone [55]. The survival benefit associated with the use of DAs was attributed by the authors to the ability of non-ergot DAs to improve motor symptoms and reduce choking and aspiration pneumonia. Also, Ernst et al. [56], based on a nested case-control study by analyzing the U.K. General Practice Research Database, found that the use of pramipexole was associated with a 24% reduction in the risk of pneumonia (RR 0.76; 95% CI: 0.57–1.02).

Considering the discrepancies with regard to the mortality found by comparing our meta-analysis with the one mentioned above, it would be appropriate to defer any definitive judgment on this point. Instead, it could be stated even now that the class of non-ergot DAs is not burdened by increased risk of incident heart failure or newly diagnosed adverse cardiac events when compared to the conventional therapy with levodopa alone. In any case, additional large-scale population-
based studies will be required to confirm the lack of unfavorable repercussions on the heart and cardiovascular system related to the prolonged use of non-ergot DAs in conjunction with levodopa.

Conclusion
In conclusion, the present meta-analysis has substantial implications for clinical practice, since the use of non-ergot DAs for PD patients was proven not to increase the incidence of heart failure. Likewise, these drugs were shown not to be associated with increased all-cause mortality or increased risk of cardiovascular events. However, further investigations are required to assess the potential benefit and risk concerning the cardiovascular system in PD patients chronically treated with non-ergot DAs. For this purpose, large population-based data, derived from trials specifically aimed at exploring the drug’s cardiovascular safety, should be systematically collected and analyzed.
