Abstract

Background: Postburn knee flexion contractures cause functional limitations of all lower extremity, not allowing the patient to walk normally, creating serious cosmetic defects, and, therefore, requiring surgical reconstruction. The anatomic features of knee flexion contractures and their treatment have been covered in literature far less than large joints of the upper extremities, and their treatment is still a challenge for many surgeons.

Methods: Anatomy of postburn knee flexion contractures in 58 patients was studied and contractures were surgically eliminated by using new approaches and techniques. Follow-up results were observed from 6 months to 12 years.

Results: Knee postburn flexion contractures were divided into three anatomic types: edge, medial, and total. Edge contractures were caused by scars located on the lateral or medial knee surface and were characterized by the presence of the fold along the popliteal fossa edge. The lateral sheet of the fold was scarred and ulcerous scars should be excised. The study is the original research of the 1st level of evidence.

Conclusion: Three anatomic types of knee scar flexion contractures were identified: edge, medial, and total. An anatomically justified technique for edge and medial contractures was trapeze-flap plasty. Total and most medial contractures were efficiently eliminated with scar excision and skin grafting; rarely was external distractor needed.

Keywords: Knee burns; Knee scar contracture; Knee contracture treatment; Trapeze-flap plasty

Introduction

Knee postburn scar flexion contractures, making up 22% of large joint contractures [1], affect the leg motion, impair the lower extremity function, present cosmetic defects, and requiring surgical treatment. The contracted scars undergo (during joint extension) severe tension, tearing, and often are converted to pathologic scars-rough, thick, solid, prone to keloid growth and ulceration. Review of literature shows that there is less research on knee scar flexion contractures, than on the large joints of upper extremities, when it comes to surgical treatment. There is no existing anatomical classification of flexion contractures that could serve as a guide, for reconstructive technique choice, which presents a clinical challenge [2]. Many surgical techniques have been described; however, an ideal method is yet to be found [3]. The most common treatment methods are based on the incisional contracture release and skin grafting or on the local triangular flap techniques [4]. Rarely, regional pedicled or free flaps and Ilizarov fixator are used. Most of these methods were tested in our institute; a high rate of complications and contracture recurrence induced us to search for a more efficient approach.

This paper presents the anatomical classification of knee postburn flexion contractures and specific techniques for treatment every type and results [5-16].

Material and Methods

Fifty-eight patients with postburn knee scar contractures were studied and operated on personally during past 16 years, from one to six years after burns; among them, 21 were male and 37 female; age ranged from 3 to 48 years, 18 were children. All patients sustained deep partial-and full-thickness burns from 9 to 28 % (mean=19%) of the TBSA (total body surface area) resulting in knee flexion contracture formation. Anatomical features of knee scar contractures were studied prior to and during the operation, immediately after surgery and periodically from 6 months to 12 years after surgery. Research was done on the possibility of the maximum use of local and adjacent tissue in reconstruction, as well as research on flap and skin graft behavior after reconstruction. Results were considered good if there was complete contracture release (full knee joint extension of at least 180° and flexion of 120°) and donor site morbidity was acceptable. Thirty-six patients studied earlier in whom incisional contracture release and triangular flaps (Y-V and Z-plasty and their modifications) were used were not included in this series.

Results

Knee flexion contractures anatomy and terminology

Specific anatomical features of knee flexion contractures were the result of burns located on the lateral joint surface (medial or lateral), or posterior (popliteal area), or all three surfaces (both lateral and popliteal) together. Corresponding with scar location, three anatomic contracture types were formed.

Edge knee flexion contracture anatomy (Figure 1)

In the case of lateral joint surface injury (38 of 58 patients (65.6%)): (a) the popliteal area (flexion surface) remained undamaged; (b) contracted scars formed a crescent fold along popliteal fossa edge; (c) the crest of the fold was the scar's edge; (d) the scars of the fold consisted of the two sheets: scar lateral (according to popliteal fossa), which the contracture caused, and healthy medial sheet, spreading on undamaged popliteal fossa. These anatomical features determined the name for this type, edge (Figure 1A). A fold's length and its protrusion differ from case to case, depending on the contracture severity. Contracture is caused only by the scar sheet in which there is a surface deficit in length, and spreads, subsiding, from the fold's crest to the joint rotation axis.

The form and size of the scar's surface deficiency (reason for contracture) must be determined since reconstruction's aim is to compensate for the deficiency with an adequate flap. The form and size of scar surface deficiency is estimated using the following steps: the scar sheet is separated from healthy skin with an incision along the fold's crest; with a Y-shaped perpendicular incision, the scar sheet is dissected from the fold's crest to the joint rotation axis level where incision is split under 45 degrees, forming a 90 degree angle. After joint extension, a trapezoid wound appeared, as a rule, reflecting the real scar surface deficiency (Figure 1B). The wound's form indicated that the flap should have a trapezoid form (Figure 1B). Both sheets have surface surplus in width.

Figure 1: Postburn knee edge scar contracture: anatomy
a: fold along edge popliteal fossa; only lateral fold's sheet is scar, medial sheet and fossa is healthy skin; planning of operation: line for scar dissection by Y-incision up to joint rotation axis, line along fold's crest and flap's borders
b: trapezoid wound (scar surface deficiency) appeared (above white strip) after scar and fat layer incision and knee extension, flap mobilized.

Figure 2: Knee medial scar contracture: anatomy and treatment with trapezoid-flap plasty
a: contracted scars covered popliteal area and formed fold along medial popliteal line, both fold's sheet are scars; wound at fold's crest
b: (next case), left- planning of operation; right- 3 pairs of adipose-cutaneous trapezoid flaps mobilized, rough ulcerous scars excised
c: left - counter flap transposition; right- two years after operation: contracture eliminated in full
d: scar surface deficit compensated with trapezoid flap.
Anatomy of the knee flexion contractures after burns of popliteal area (Figure 2)

Scars in popliteal area observed in 14 out of 58 patients (24.1%) and: (a) formed a crescent fold located along the medial line of popliteal fossa; (b) both sheets of the fold were scarred and spread from the fold’s crest to the popliteal fossa’s edges (Figure 2A). These two anatomical features determined the name for this type, medial, which occurred in 5 cases. Both scar sheets of the fold have a surface deficiency in length (cause of a contracture) and surface surplus in width which allowed contracture treatment with local flaps. The fold can be small and short or may spread to the thigh and leg. The form and size of the scar sheet surface deficiency in length (the cause of the contracture) is estimated the following way: the fold sheets are divided with an incision along the fold’s crest; contracture is released by a perpendicular Y-shaped incision from the fold crest to the popliteal fossa edges. After joint extension, as a rule, the trapezoid wound appeared in both scar sheets, which was maximal at the fold crest and spread, subsiding, to the popliteal fossa edges (Figure 2B). Besides, the fold’s sheets have a surface surplus in width, which allow the contracture to be eliminated with local tissue (Figure 2C). Consequently, adequate contracture treatment of knee medial contracture can be performed by means of surface deficiency compensation with the trapezoid flaps.

In 9 patients, scars in popliteal area were pathological-rough, thick, red, keloid – and, therefore, found unfit for plastic (Figure 2). Scars in popliteal area undergo severe tension while walking; therefore, the scars tear first in the maximal tension zone (crest); after that, a small wound gradually converted to a chronic ulcer (Figure 2A, B); the normal scars became pathological which were inconvenient for the reconstruction use.

Total knee joint contracture (Figure 3)

After deep vast burns, scars tightly surrounded the knee, creating severe scar surface deficit without fold (6 patients, 10.3% of the total number). Reconstruction with a local flap was excluded. These anatomical criteria characterized a total. Due to severe tension while joint was extended, scars were converted to pathologic (solid, rough, thick), prone to necrosis and ulceration. Along with the scar contracture, deep burns could injure the articular structures (two of 6 patients), making the contracture more severe and complex for treatment.

Reconstructive Techniques

The anatomical features, specific for every contracture type, predetermined an adequate surgical technique choice.

Reconstructive techniques for edge contracture elimination (38 patients)

Depending on contracture severity, ulceration presence, and patient’s age, several techniques were used.

One-flap technique

In the case of mild-to-moderate contracture, reconstruction was performed with one trapezoid flap. Planning consisted of several lines drawn: along the fold crest for separating scars from healthy skin, a Y-shaped perpendicular line for scars dissection. The following lines marked flap boundaries (Figure 1A). The first incision separated the scar sheet from the healthy skin; then, the scar sheet and subcutaneous fat layer were dissected with a Y-incision from the fold crest up to joint rotation axis. Due to a Y-shaped incision and after knee joint extension, the wound's edges diverge, the wound accepted, as a rule, trapezoid shape, which presents a real contracture cause, and wound's end, the M-form (Figure 1B). According to the wound size and form, but nearly 30% wider, the adipose-cutaneous flap was mobilized in popliteal area up to the opposite popliteal fossa's edge, including the medial fold's sheet and all subcutaneous fat layer. The flap end was nearly 5 cm in width and included a part of the fold's crest; the flap's length equaled a distance among popliteal fossa's edges plus medial healthy sheet (8-10 cm). The flap's end was incised nearly 1 cm in depth for connecting with the same form (M) of wound's edge. The flap was transposed on the wound with tension until the flap's end achieved a wound's end. Angles of the scar sheet were approached to flap's base and covered the small donor wounds aside the flap (one-flap technique; Figure 1C, upper).

Three-flap technique (Figure 2)

In case of more severe contracture, scar surface deficit and trapezoid wound, formed after scars dissection, were larger than in previous case (Figure 2A and 2B). Therefore, the donor wounds on both sides of the trapezoid flap were covered with adipose-scar trapezoid flaps, prepared from the scar sheet (Figure 2C and 2D).

Multiple-flap plasty (Figure 3)

Severe contracture and scar surface deficit that is caused by a long fold (Figures 3A-3C). The fold's sheets on all of the extent were converted to adipose-cutaneous and adipose-scar flaps. Counter flaps transposition allowed the contracture release without skin grafting (Figure 3D). Ulcerous scars, located at the fold crest, were excised first; then, the trapeze-flap plasty continued in the usual manner.

In children (under ten years), the contracted scars, causing a mild edge contracture, located on the lateral knee joint, hip, and leg surfaces, could be excised from the fossa’s edge up to joint rotation axis (strip 5 to 7 cm in width), eliminating contracture and deformation (Figure 4A and 4B).
and 4B). Due to good tissue elasticity and displacement of the adipose-cutanous layer, the wounds were primarily closed without tissue mobilization.

**Knee medial contracture elimination techniques (14 patients)**

Two procedures were used. If scars of the fold were pliable and thin, the fold's sheets cars used for plasty (5 patients). The goal was to fully convert the fold's sheets in the flaps (Figure 5A and 5B). First, the ulcerous fold's crest was excised, and fold's sheets were divided along all fold's crest. As the fold has a crescent form, the Y-shaped incisions from the fold's crest to the popliteal fossa's edges converted the sheets in the flaps which, as a rule, accept trapezoid form. After knee extension, the wounds also accept the trapezoid form. The flap's end was nearly 5 cm in width and included part of the fold crest, the flap base corresponds to the popliteal fossa's edge. Scars and full subcutaneous fat layers are included in the mobilized flap, having steady blood supply. Flaps were counter transposed with tension. Flap's ends were approached to the opposite flap's base (Figure 5C).
Depending on contracture severity and fold length, one or several pairs of the flaps were elevated until contracture could be fully released and wound covered with flaps. In the case of severe contracture, the flaps covered the central knee flexion zone; residual wounds were skin grafted (Figure 6). The rate of lengthening always exceeded 100% (sum of all flaps in their middle width minus the length of the crest involved in plasty) [17-25].

Scars, covering popliteal area, in 9 cases (Figure 7A) were pathological (rough, thick, solid, and ulcerous) and impossible
to convert in the flaps. Such matured scars were excised through intermediate layer, which was formed during scar maturation from solved scar's inner surface and has scanty amounts of vessels (Figure 7B). Only after scars’ excision, the knee is extended with caution. For fatty layer tearing prevention, the surgeon lays its palm on the wound, creating pressure during knee extension. The split transplants placed on such wound's surface grow well; their shrinkage is minimal, what prevents a contracture recurrence (Figure 7C and 7D).

**Total knee contracture treatment**

The operation consisted of pathologic ulcerous scars excision in the popliteal area and lateral joint surfaces. Manual knee extension was combined with pressure on the wound by the surgeon's palm to prevent fat tissue tearing and solid structure exposure. In cases of severe total contractures, complicated by ulcers (Figure 8A and 8B), pathologic scars were excised in one block with ulcers; the exposed vessels and nerves were covered with the local fat tissue transposition and the wound was covered with skin grafts (Figure 8C). If necessary (two patients), external distractor was applied (Figure 8D).

After surgery, the usual gutter splint was applied for 3-5 weeks with 5-day antibiotic therapy.

**Results of Operations**

Knee flexion contractures were eliminated fully in all 58 patients. In 39 patients with edge contractures, the adipose-cutaneous trapezoid flaps and whole adipose-cutaneous layer (in children), rose from popliteal area, were alive and tolerated tension well (Figure 1 and 4). During long-term observation, the flaps did not shrink, but continued to grow, especially in pediatric patients, preventing the contracture recurrence, normalizing skin tension and contours of the popliteal fossa. In 2 cases, a marginal superficial necrosis in adipose-scar flaps occurred; wounds healed under dressings without consequences.

Follow-up results were functionally excellent; donor site (popliteal fossa) preserved normal outlines without deformities with operation scars. In case of medial contractures, after trapeze-flap plasty (5 patients), no scar flap's loss was observed: good follow-up results were achieved (Figure 2). Skin grafts in 9 patients covered wounds without complication and were functioning well during all terms of observation, without signs of ulceration and re-contracture (Figure 7). Total contracture successfully

eliminated in all 4 patients treated only by wide scar excision and skin grafting; in 2 patients, along with the scars excision and skin grafting, the external distraction was used with good outcomes (Figure 3). The skin transplants, covering large wound, converted to well-functioned skin (Figure 8); therefore, wide scar excision and skin grafting significantly improved all extremity appearance.

Discussion

Knee flexion contractures need to be reconstructed as early as possible to improve the loss of a patient's activity and prevent kyphosis development. The goal is to return the patient to society in a normal function and appearance as possible [25-34]. Literature data presents the following known classifications and techniques proposed for knee contracture treatment.

Classification and terminology

Literature analysis shows that the knee flexion contracture anatomy and treatment have been researched less than other big joints. There is no anatomical classification; nest names are used: web, straight linear, wide, linear, wide and quadratic, wide linear; long. Ogawa and Pribaz [33] classified knee contracture into 5 forms: linear (anterior, posterior, tibial or peroneal); broadband (the same subdivision as previous form); broadband contractures extended to neighboring surfaces; broadband contractures of entire circumferences; others [1-5,16,18,30-33].

Listed classifications (lineal, wide, broadband, long, web) determine a scar's form but do not disclose complete anatomical contracture form and its cause; they do not serve as a guide for the adequate technique and flap choice and not allow the results comparison of their application.

According to our data, contracture formation is determined by scar location on the joint: lateral surface, popliteal surface or circumference. Laterally located scars form a fold along the popliteal fossa edge, allowing the contracture treatment with local tissue. Contracture is caused only by a lateral scar sheet due to scar surface deficiency in length which has a trapezoid form. The crest of the fold is the scar's edge. Therefore, such contracture is named as edge type. Scars in popliteal area form the fold (contracture cause) along with medial popliteal line; both fold's sheet are scars; therefore, the contracture named as medial. Both sheets of the fold have a trapeze-shaped surface deficit in length (contracture cause) and surface surplus in width. Surface surplus in both fold's sheets allows contracture elimination with local tissue, compensating scar surface deficiency. Scars, tightly surrounding joint without fold, what excludes local-flap plasty, named as total.

Incisional contracture release and wound resurfacing with skin grafts [6]; incision with progressive stretch load [7], quadra Z technique [3], MacCanley and Asuku [6] write that incisional or excisional release and skin grafting is frequently the first line of therapy with excellent long-term results.

Our experience showed that after scar incision, during knee extension, the scar edges diverge, involving the fat tissue, which is torn, baring solid popliteal structures and creating a soft tissue defect. The scars aside the wound continue to stay in contracted condition, creating residual contracture. The skin grafts, placed on such wound, shrink and contracture recurs (8 cases). Therefore, we no longer apply the incisional release in case of medial and total contractures caused by scars located on the joint's flexion surface. Pathological scars excision on all popliteal area yields the positive outcome. In case of edge contracture, the fatty layer is dissected up to deep fascia; appeared soft tissue defect (scar surface deficit) is resurfaced with popliteal adipose-cutaneous flap.

Reconstruction with local flaps

Z-plasty and its modifications [8,9]. Dougherty et al. [4] write that for medially or laterally located (edge contracture) skin flaps are preferable to skin grafts; Z-plasties or V-Y advancement flaps may be sufficient in most cases. Buis et al. [10] reported that a conventional Z-plasty on postburn scar tissue frequently leads to varying degrees of necrosis of the tips of the transposed flaps. Proposed interpositional skin-flap procedure [11] is Z-plasty modification.

- Seven flap plasty [17]; method consists of two half Z-plasties and one W-M plasty;
- Circumferential incision technique which is similar to the double opposing V-Y plasty [18].

Efficacy of V-Y procedure depends on depth of the flap's advancement only which is restricted, as the flaps are not mobilized [19]. Gusum [14] concluded: V-Y technique use undermined flaps, which can not close the defect completely.

Other flaps and techniques are recommended for concrete knee contracture or all scar contractures, including the knee: - Z-lengthening of tendons and gastrocnemius muscle flap [20]; distally-based fasciocutaneous thigh flap [21,22]; medial sural perforator plus island flap for the reconstruction of postburn knee [23]; proximally-based sural flap [24,25]; posterior calf fascial flap [26]; anterolateral thigh free flap [21].

Ilizarov technique [27], after which a high rate of contracture recurrence have been noticed [28]; combined Ilizarov technique and free flap for severe recurrent flexion contracture treatment [29]. Efficacy of proposed techniques and indications of their use impossible to estimate and determine as a contracture type stayed unknown. Dougherty et al. [4] discern two forms: (a) medially or laterally with unburned skin posteriorly (popliteal fossa) which is successfully treated with local triangular or transposition flaps (the first choice) and (b) contracture of the entire popliteal area which is treated with incisional release and skin grafting.
