Abstract

The International Diabetes Federation (IDF) does not justify the evaluation of metabolic syndrome (MetS) in children aged less than 10 years, unless they have a family history of risk factors. The prevalence of overweight and obesity in the Northwest of Mexico has increased in recent decades, making it possible to consider that MetS is already present in this group of population.

Objective: The primary objective of this study was to determine the prevalence of metabolic syndrome in children aged 6 to 9 years living in rural (RA) or urban (UA) areas of Northwest of Mexico. A secondary objective was to find adequate criteria to diagnose the prevalence of MS in children.

Methods: Participated 268 school-aged children in a random-selected cross sectional study. Anthropometric and blood pressure measurement were performed, and biochemical indicators were analyzed. MetS was defined as the presence of three or more risk factors and diagnosed using three different criteria. One of them according to what was proposed by the International Diabetes Federation (IDF) for children and two additional criteria proposed by this study considering suitable cutoffs for age for lipids and blood pressure.

Results: The general prevalence of MetS according to the three different criteria used was as follows. 1) IDF criteria, 4.1%; 2) using cutoffs suggested for age for lipids and blood pressure and taking into account waist circumference as a criterion for MetS, 6.3%; and 3) cutoffs suggested for age, lipids and blood pressure without considering waist circumference as a criterion for MetS, 10.4%. Children living in the RA with a history of obesity and cardiovascular disease had higher waist circumference, triglycerides, and very low-density lipoprotein-C, and children from the UA had higher systolic and diastolic blood pressure, and higher levels of glucose and insulin.

Conclusion: MetS is present in children aged 6 to 9 years in the northwest region of Mexico, with higher proportions of the syndrome observed in overweight and obese children. The second criteria used in this study could be the most suitable for diagnosis of MetS, and the third criteria, for children at higher risk for cardiovascular disease and type 2 diabetes mellitus associated to heredity factors.

Keywords: Metabolic syndrome; Obesity; School-Aged Mexican children; Cardiovascular disease; Type 2 diabetes mellitus

Introduction

Overweight and obesity are highly associated with metabolic syndrome (MetS). This is defined as a clustering of metabolic abnormalities characterized by risk factors that are associated with cardiovascular disease and type 2 diabetes mellitus (T2DM). These factors are abdominal obesity, lipid profile alterations, glucose intolerance, and hypertension [1]. The presence of MetS increases the risk of developing cardiovascular disease and T2DM [2]. For adolescents, the evaluation criteria are not well defined and there is no accepted definition to diagnose MetS [3]. The International Diabetes Federation (IDF) [4], does not justify the evaluation of MetS in children less than 10 years old, suggesting that the presence of MetS is out that its presence is unlikely in this population. Nevertheless, IDF states that more studies are needed to corroborate this statement.

One of the difficulties in evaluating MetS in children is the constant change in the level of insulin during childhood and the presence of physiological insulin resistance during puberty [5]. However, evidence indicates that people who develop diabetes in adulthood had higher body mass index (BMI) and subscapular skin fold as well as higher levels of glucose, triglycerides, and insulin, higher blood pressure, and lower levels of HDL-cholesterol (HDL-C) during childhood than those who do not develop diabetes [6]. Additionally, the American Pediatric Association suggests that cardiovascular risk factors be evaluated in children between 2 and 10 years of age when they have family history of cardiovascular diseases [7].

Currently, research on MetS focuses on identifying its components in different populations and at different ages as well as developing a useful definition for clinical and epidemiological practices. In addition to the traditional components of MetS, researchers are considering other indicators that could be helpful in identifying people at higher risk, such as acanthosis nigricans (AN) and inflammatory markers [8,9].

In Mexico, T2DM and cardiovascular diseases are the main causes of mortality in the adult population [10]. Risk factors leading to these pathologies could be present during childhood mainly due to heredity or life style factors such as inadequate diets higher in carbohydrates or fat, together with low levels of physical activity [11,12].

In this context and according to data from the National Health and Nutrition Survey in Mexico in 2012, the state of Sonora, located in the...
northwest region of Mexico, is one of the states in the country with a higher prevalence of childhood overweight and obesity (36.9%). Both rural and urban areas are affected, although in different ways; there are more overweight (24.8%) than obese (6.4%) children in rural areas, whereas the urban areas have more obese (19.4%) than overweight (18.3%) children [13]. Among the complications associated with excess body fat are insulin resistance [14], non-alcoholic fatty liver disease, hypertension, dyslipidemias, sleep disorders, orthopedic problems, and psychological and social issues [15].

The evaluation of MetS in children and adolescents is important for timely prevention and control of non-communicable disease development such as heart disease and T2DM. Therefore, the primary objective of this study was to determine the prevalence of metabolic syndrome in children aged 6 to 9 years living in rural and urban areas of Northwest of Mexico. A secondary objective was to compare MetS prevalence differences based on three criteria in a sample of children from Sonora, Mexico and determine the most appropriate criterion to diagnose it in a pediatric population.

Materials and Methods

Study design and sample selection

For this study, a cross-sectional sample of school-aged children aged 6 to 9 years was assessed. Eighteen public elementary schools located in two different areas (rural and urban) in the state of Sonora in northwest Mexico participated in the study. In the rural area, 7 schools from different towns were involved. In the urban area, 11 schools located in the city of Hermosillo (the capital) participated in the study. The rural and urban areas were defined according to the criteria established by Villalvazo [16], who defined a rural area as having less than 15,000 inhabitants. A total of 295 children participated in the study.

Study protocol

The experimental protocol was approved by the Ethical Review Board of Centro de Investigación en Alimentación y Desarrollo A.C. We used simple random sampling for the selection of the schools. Forty invitations were left in each school, inviting parents who had children between 6 and 9 years old to participate in the study. Parents and children who attended the invitation, received a detailed explanation of the protocol and provided informed consent. The parents answered a clinical questionnaire about family history of diabetes or cardiovascular risks, current medical conditions, and medication use.

A standard questionnaire was used to collect information about socio-demographic characteristics, and patient’s medical and family history during face-to-face interviews conducted by trained staff. Family history of obesity, diabetes, and cardiovascular disease were defined as the existence of these conditions in at least one first-degree relative.

Anthropometric measurements were performed according to standard procedures. Body weight was measured using an electronic scale with a capacity of 0 to 150 ± 0.05 kg (AND FV-150 KA1; A&D Co., Japan), and height was measured using a portable stadiometer (Holtain Limited Dyfed, Britain, UK). BMI was calculated using weight and height (kg/m²) and BMI for age z score, height for age z score, and weight for age z score were calculated using the Anthro Plus software [17]. Obesity was defined following World Health Organization (WHO) criteria for children of the same age. Waist circumference (WC), was measured with non-elastic tape (Lafayette Instruments, USA) at the midpoint between the lower rib margin and the iliac crest, perpendicular to the long axis of the body, with the subject standing balanced on both feet. Body composition was measured using bioelectrical impedance analysis (Impedimed IMPS510). Since we could not assess a hydration status of the children before measurement, we applied a brief clinical questionnaire to the parents in order to know if their children presented illness or diarrhea episodes 5 days before the evaluation. If the answer was positive, the child was not included in the study. Total body fat and lean mass were obtained using the Ramirez-Lopez formula developed for the population of school children living in Sonora [18]. Body fat percentage was classified according to Freedman’s values for age and gender [19].

Blood pressure was measured according to the technique proposed by the National High Blood Pressure Education Program (NHBPEP) for children and adolescents [20] after 5 minutes of rest in a sitting position with the child’s feet on the floor and their arms supported at heart level. Two measurements were performed at 10-minute intervals using mercurial sphygmomanometers (Desk Model Mercurial Sphygmanomanometer, Model 100, China Meheco Medical instrument, RPC) with an appropriate cuff for the arm diameter. Hypertension was defined as the average systolic (SBP) or diastolic (DBP) blood pressure level greater than or equal to the 95th percentile for the child’s sex, age, and height. AN was defined as a skin darkening and thickening at the neck [21]. The determination of AN child was assessed by a trained individual.

Biochemical analyses

 Plasma obtained after overnight fasting was used to determine plasma glucose, total cholesterol (TC), HDL-C, triglycerides, and insulin. Two fasting (12-h) blood samples were collected from each subject on 2 different days. Blood was collected in tubes containing 0.15 g/100 g EDTA to determine plasma lipids. Plasma was separated by centrifugation at 1500 g for 20 min at 4°C then placed into vials containing phenyl methyl sulfonyl fluoride (0.015 g/100 g), sodium azide (0.01 g/100 g), and aprotinin (0.01 g/100 g).

 TC was determined using an enzymatic method (CHOD-PAO) with Roche-Diagnostic standards and kits [22]. HDL-C was measured in supernatant after precipitation of apo B-containing lipoproteins [23], and low density lipoprotein (LDL)-C was determined using the Friedewald equation [24]. Triglycerides were measured using an enzymatic method (GPO-PAP) with Roche-Diagnostics standards and kits [25]. Means of two blood draws were used.

 Plasma glucose was determined using an enzymatic method (GOD-PAO) with Roche Diagnostic kits [26]. Fasting plasma insulin concentration was determined by enzyme-linked immunosorbent assay (ELISA) using a sandwich type immunoassay (ALPCO Diagnostics, NH, USA). The homeostasis model assessment (HOMA) [27] was used to calculate insulin resistance (IR) according to the following equation: IR = (HOMA IR) = fasting insulin (µU/mL) fasting glucose (mmol/L) ÷22.5. The HOMA model has been shown to be a reliable method for measuring insulin resistance in various populations when other more invasive methods are not feasible [28]. The HOMA-IR value of 3.4 was chosen as the reference value to define IR [28] and the insulin blood concentration was classified as normal, borderline, or high [29].

Definition of metabolic syndrome

Because there is no single accepted criteria for the diagnosis of MetS in children aged 6 to 9 years, the presence of MetS in this population was determined using three different criteria as follows: 1) according to the definition proposed by IDF [4] for children aged 10 years, considering the presence of central obesity as a mandatory condition for diagnosis coupled with the presence of two or more additional risk factors.
factors; 2) considering the presence of central obesity according to the provisions of the IDF [4], but using predefined cutoffs for lipids specific for children [30] and blood pressure [20]; 3) establishing the presence of three or more risk factors regardless of central obesity as a mandatory condition and using predefined cutoffs determined by the IDF [4] for waist circumference and glucose, the National Cholesterol Education Program (NCEP) criteria [30] for lipids, and the NHBPEP criteria [20] for blood pressure (Table 1).

Central obesity was defined as a waist circumference value at or above the 90th percentile for sex, age, and ethnicity from the IDF definition [4]. For the lipid profile, we considered the cut-off values was taken from the IDF and considered as 100 mg/dL or higher.

### Statistical analysis

Normality of the data was verified and descriptive statistics were performed to show the study population characteristics by rural/urban area. Data are presented as means ± standard deviations and as medians and interquartile ranges accordingly. Normality and equality of variances were evaluated and the tests were used accordingly. Two-sample Student’s t-test was used to compare both areas of study. For non-normal variables, we used the Mann Whitney U Test. For non-equal variances, the Aspin Welch p value was selected. The Chi-squared test for Independence was used to compare frequencies. Differences with p<0.05 were considered significant. The kappa coefficient was used to test the level of agreement for the three definitions. All data were analyzed using NCSS 2007 (Number Cruncher Statistical System for Windows, Kaysville, Utah, USA) Software.

### Results

Children’s anthropometric characteristics by area (rural and urban) are presented in Table 2. The mean age of the children was 7.4 ± 1.03 years, ranging from 5 to 10 years. No statistically significant differences were observed between rural and urban areas in the anthropometric variables, blood pressure and the AN indicator (p>0.05). According to the z BMI/A: the prevalence of overweight and obesity was 31.1% in rural areas and 32.9% in urban areas. Waist circumference was at or above the 90th percentile in 10.1% of children in rural areas and 12% in urban areas. Likewise, children with moderate and high body fat percentage were observed in both study areas: 26% and 33% in rural and 27% and 36% in urban areas, respectively.

There were statistically significant differences between the urban and rural areas in some metabolic variables. Fasting blood glucose, insulin, and the HOMEA index were higher in the urban area, whereas concentrations of triglycerides, HDL-C, and very low density lipoprotein (VLDL)-C were higher in the rural area (Table 2).

According to the American Diabetes Association [31], fasting glucose values in children with normal, impaired, and probable diagnosis of diabetes are 86.1 mg/dL, 108.5 mg/dL, and 128.4 mg/dL (p<0.01), respectively. Figure 1a shows the classification of the study population according to their blood glucose concentration.

Glucose data were divided according to normal, borderline, and high insulin blood levels. There were no differences in concentrations of glucose (p=0.99) relative to insulin levels, even when we found borderline and high values of insulin (Figure 1b).

According to the HOMA index, insulin resistance was present in 9 children from the rural area (7.5%) and 22 from the urban area (14.8%). There were no statistically significant differences between study groups (p=0.06). AN, which is associated with high levels of insulin, was found in 15 children including 9 from the rural and 6 from the urban areas (Table 2). This indicator was observed only in children with a high body fat mass.

Results of the anthropometric and metabolic characteristics in the population stratified by family history of obesity, diabetes, and cardiovascular disease are shown in Table 3. Children with a history of obesity had a significantly higher weight/age (W/A) and percentage of fat mass compared to children with no familiar history of obesity. Those with a history of diabetes had higher BMI/A and waist circumference, and children from families with a history of cardiovascular disease had higher systolic blood pressure, DBP, TC, and LDL-C compared with children without a family history of cardiovascular disease. Particularly in the rural area, a family history of obesity and cardiovascular diseases was present in children with a higher waist circumference (58.5 vs. 53.8 cm, p<0.02; 59 vs. 54.2 cm, p<0.01). In contrast, urban children had higher SBP (94.46 ± 11.97 vs. 88.17 ± 10.98 mmHg, p<0.001) and DBP (63.36 ± 12.92 vs 57.60 ± 10.08 mmHg; p<0.001) when a family history of obesity and cardiovascular diseases was present.

Table 4 shows the proportion of children with MetS according to the different definitions used in the present study. For the first criteria suggested by the IDF [4], MetS was present in 11 children (4.1%). In the rural and urban areas, 2.5% and 5.4% of the children had MetS,

![Figure 1](image_url)
and the differences between groups was not significant (p=0.24). The second criteria for MetS (Table 5) considered abdominal obesity plus two other risk factors according to the NCEP [30] and NHBPEP [20] percentiles. MetS was found in 17 children (6.3%), 5.0% from the rural and 7.4% from the urban areas, with no significant differences between groups. The third criteria for MetS diagnosis considered children with three or more risk factors for MetS and the presence of abdominal obesity was not obligatory. Of the total population, 10.4% had MetS, and the same percentage of children with MetS was present in both areas of study (rural 10.1% vs. urban 10.7%, p=0.86). The reliability analysis using the kappa coefficient (0.6487, p=0.000) showed that the agreement was substantial in the total population.

Discussion

This study demonstrates that MetS is present in children aged 6 to 9 years living in urban and rural areas of northwest Mexico. In this study...
population, overweight and obesity represented one of the risk factors for MetS. In both the rural and urban areas, the prevalence of obesity was elevated (31.1% and 37%, respectively). The percentage of urban children with obesity was higher than that reported by the Nutrition and Health National Survey 2012 [32].

Towards the end of the first year of life, a physiological loss of fat mass takes place, so that in normal conditions a child between 5 and 6 years should be physiologically thinner. When a 6-year-old is an obese child, the probability of persistent obesity increases by 50% [33]. Obesity in parents influenced the development of obesity in their children and this influence seemed higher when the child was aged less than 10 years [33,34]. In this study, the results from the family history questionnaire on chronic diseases showed that children from the rural area with a family history of cardiovascular diseases and obesity had higher waist circumference. In contrast, children from the urban area with the same family history had higher systolic and diastolic blood pressure (data not shown). We do not have a clear idea of the differences between urban and rural children, as they have similar family history. A possible explanation is that in the urban areas, there is a greater tendency to consume fast foods that typically have a high sodium content, which probably could be affecting the gene expression associated with blood pressure. Kuschinr and Mendoza mentioned that the risk of developing hypertension is higher when both parents have the disease [35].

Beside heredity, other factors that may contribute to the growing prevalence of obesity and its complications in this population are low physical activity and an inadequate diet. Although data on dietary habits and physical activity were not collected. Results from others studies [36-38] in urban locations of the same region showed that children consumed a hypercaloric diet, with adequate quantities of protein and fiber but excessive amounts of simple carbohydrates and saturated fat and a low quantity of polysaturated fat. Those studies also showed that most of the children were sedentary [36,38]. The development of obesity secondary to genetic or excessive consumption of food has been proposed as a risk factor for developing metabolic alterations including insulin resistance and diabetes mellitus [39]. Transnational food chains have made energy-dense, low-cost food available and accessible to Mexican children in a community environment where food regulation is still scarce [40].

The analysis of the metabolic profile showed that children from the rural area had more alterations in their lipid profile, with higher triglyceride and VLDL-C values than children from the urban area. In contrast, children from the urban area had more alterations in glucose metabolism, with higher concentrations of glucose and insulin and higher HOMA than children from the rural area. These results suggest that children from the urban area at greater risk for developing heart disease or diabetes, possibly due to risk factors related to lifestyle. Studies on the migration of people from rural to urban areas have reported similar changes in body composition and clinical markers associated with their new lifestyle, which involve higher consumption of energy-dense foods and less physical activity [41,42].

A simple analysis of fasting blood glucose does not determine the diagnosis of diabetes, but it may be the first step in its detection. In this study, we classified fasting blood glucose concentrations according to the American Diabetes Association [31]. Of the total population of the study, 31.3% (21% rural, 38.3% urban) of children had impaired fasting blood glucose. These children are probably producing more insulin to compensate for the elevated glucose, but the two are not balancing each other out [43]. We could assume that this situation has progressed for some time and could turn into T2DM in the future.

T2DM begins with reduced insulin action due to an impairment in the ability of the target cells to respond to this hormone, which leads to insulin resistance. During this process, there is a decrease in the peripheral consumption of glucose and also in hepatic glycogenesis, and an increase in glycogenolysis with results in hyperglycemia. Also, β cells from the pancreatic islet cells hypersecrete insulin to compensate for the excess glucose, producing hyperinsulinemia and normoglycemia. When the cycle is exhausted, it leads to glucose intolerance and, in later stages to T2DM [43,44].

We found children with insulin resistance in both areas (7.5% rural, 14.8% urban, p=0.06). Even when we did not detect significant differences between groups, the proportion of children with insulin resistance was higher in the urban area. Secondary to obesity, insulin resistance may be a common etiopathogenic mechanism for hypertension and dyslipidemia. Generally, children with obesity have a higher prevalence of hypertriglyceridemia and low levels of HDL-C [45]. In adipose tissue, hyperinsulinemia increases lipolysis, leading to

**Table 5**: Anthropometric characteristics and metabolic profile according to the presences of metabolic syndrome (MS) with abdominal obesity as an obligatory factor (second criteria used in this study).
more availability of free fatty acids, an increase in the hepatic synthesis of VLDL, and a decrease in HDL-C [46].

AN was found only in children with high body fat mass, and this coincided with insulin resistance being present only in children with high fat mass. The prevalence of high SBP and/or DBP was 16% rural vs 11.4% urban, the presence of hypertension at an early age is might be an early sign of glucose intolerance [47] and a risk factor for coronary disease [48].

Another risk factor for coronary disease is dyslipidemia. In this study, 32.1% of children had hypertriglyceridemia and 19% had low HDL-C. Other studies in Sonoran children reported low levels of HDL-C and the predominant subfraction was HDL-C, which is associated with higher cardiovascular risk [38]. Obesity, hypertension, hypertriglyceridemia, low HDL-C, and impaired glucose are components of MetS.

One of the most important goals of this study was to evaluate the prevalence of MetS in children using three different diagnostic criteria and determine which of them might be more appropriate for the diagnosis of MetS in a pediatric population. The first criteria used for the diagnosis of MetS in this study were the one according to the IDF [4] for 10-year-old children. These criteria use cutoffs for adults for the biochemical indicators and account for the presence of waist circumference ≥ 90th percentile for the diagnosis of MetS. The general prevalence of MetS using these criteria was 4.1% (2.5% rural; 5.4% urban). The IDF does not consider the presence of MetS in children aged < 10 years and does not recommend its diagnosis unless the children have a family history of risk factors [4]. This study demonstrates that even when criteria for adults is used, there are children with MetS in the region of Sonora. A study by Elizondo-Montemayor et al. [49] using the IDF criteria [4] in overweight children age 6 to 12 years from Mexico City reported a prevalence of MetS of 6.7%. When they observed age groups of 6-9 years and 10-12 years, the prevalence of MetS was 7.3% and 5.9% (p=0.91), respectively. These authors mentioned that there were more children with MetS in the younger age group, and this may be due to the fact that the percentage of children with waist circumference above the 90th percentile [4] was significantly higher (p<0.001) in the group of children aged 6-9 years compared with the older age group.

Another study done in Campeche, México, used the same IDF criteria [4] and reported a prevalence of 20% MetS in adolescents aged 11 to 13 years. Nevertheless, only obese participants (BMI ≥ 95th percentile) were included [3].

The second way in which we determined the prevalence of MetS also considered the IDF criteria [4] using a waist circumference ≥ 90th percentile as a condition for the diagnosis, but also employed adequate cutoffs for metabolic measurements in children aged 6 to 9 years provided by the NCEP [30] for the lipid profile, and by the NHBPEP [20] for blood pressure. Thus, the observed prevalence of MetS in the total study population was 6.3% (5.0% rural vs. 7.4% urban, p=0.43). Thus, the ratio obtained was similar to that reported by Elizondo-Montemayor et al. [49] in children aged 6-9 years. In this study, 32.1% of children had hypertriglyceridemia and 19% had low HDL-C, which is associated with higher cardiovascular risk [38]. Obesity, hypertension, hypertriglyceridemia, low HDL-C, and impaired glucose are components of MetS.

The third way to diagnose MetS did not take into account the presence of a waist circumference ≥90th percentile as a condition for evaluating MetS and used lipid profile metabolic indicator cutoffs for children aged 6 to 9 years from the NCEP and blood pressure criteria from the NHBPEP. Thus, the prevalence of MetS using these criteria was 10.4% (10.1% rural vs. 10.7% urban), and 32.1% of the children presented with AN. When we diagnosed MetS this way, children with a normal body composition met this criterion because other risk factors like impaired fasting glucose, hypertension, hypertriglyceridemia, or low HDL-C were present. Even without considering obesity, some children may have altered metabolic factors, possibly due to genetic factors that put children at risk. High levels of TC, LDL-C, plasma glucose, and high blood pressure are risk factors that could be influenced by family history due to shared genetic and environmental factors [5].

Considering central obesity as the major factor for the diagnosis of MetS may underestimate the risk of developing cardiovascular diseases and T2DM because it excludes children without obesity who have other metabolic alterations.

The proportions of MetS identified in this population of children varied depending on the criteria used. We hypothesize that the IDF [4] criteria could underestimate the prevalence of MetS in children aged less than 10 years because the cutoffs for the lipid profile and blood pressure are not adequate for this age group. Instead, the second criteria included cutoffs suggested for this age from the NCEP [30] and the NHBPEP [20], which may detect more accurately children with MetS. The third criteria for evaluation of MetS included children with a normal waist circumference but who presented with three other risk factors. This third way of diagnosing MetS could be useful for identifying children at risk for cardiovascular and T2DM due to heredity factors.

We recognize that one of the limitations of this study was that we did not collect data on dietary habits and physical activity as factors related to obesity; however, data from recent studies were available for a proper discussion. The main strength of this study is that we measured MetS in children aged less than 10 years from rural and urban areas. We established three different criteria for evaluating MetS in children, and all the techniques used were applied by trained personnel.

Conclusions

This study demonstrates that MetS is present in children aged 6 to 9 years living in a community with serious problems of obesity and cardiovascular diseases. We also demonstrate that MetS is more prevalent in overweight and obese children. The second criteria used in this study could be most suitable for diagnosis of MetS in a pediatric population because it takes into account the appropriate cutoffs suggested for this age. Considering abdominal obesity as an obligatory factor for the diagnosis of MetS could underestimate the number of children at risk for cardiovascular diseases and T2DM because the criteria exclude children without abdominal obesity but who do have metabolic alterations. Therefore, MetS should be diagnosed using an age-appropriate definition. Our information suggests that metabolic problems in children from an urban area are at increased risk for heart disease and diabetes compared to the rural area.

Because obesity is associated risk factors for cardiovascular diseases and T2DM, health promotion programs should consider the combination of genetic and environmental factors. If these factors are detected and controlled in time, the development of non-communicable diseases related to MetS could be prevented.
Implications for School Health

The development of metabolic syndrome or related-conditions including obesity, hypertension, cardiovascular diseases, and type 2 diabetes mellitus in school-aged children could interfere with their adequate physical and mental development. The diagnostic criteria evaluated in this study may be useful to develop a useful definition for clinical and epidemiological practices of pediatric population in risk of chronic diseases.

Human Subjects Approval Statement

This research was approved by the Ethics Committee of the Food and Development Research Center (CIAD) (Document code CE/018/2009).

Acknowledgments

We thank the children and their parents for their participation. We also thank the School Breakfast Program of Sonora (DIF, Sonora) for supporting this study.
