Abstract

Tuberculosis (TB) remains a serious threat for human health. The majority of TB cases arise from latent *Mycobacterium tuberculosis* infection (LTBI). Therefore, latent *M. tuberculosis* infection (LTBI) is a major reservoir of the pathogen, and every effort thus should be made to diagnose LTBI to ensure completion of the treatment of it. TB is endemic throughout most of the tropics, in which parasitic infections are prevalent as well. It was reported that Helminth infection, including hookworm, is a risk of active TB, but its effect on the establishment of LTBI is unknown. In this study, we conducted a cross-sectional survey of LTBI and parasitic infections among 240 children from schools situated along the shores of Lake Victoria in Mbita district, Kenya. Blood samples were analyzed for LTBI and enteric parasite infections. Among the 240 children examined, 75 (31.3%) were found to have LTBI. Of the 75 children with LTBI, 10 children (13.3%) were found to be positive for hookworm eggs (odds ratio: 3.02; 95% confidence interval: 1.14-7.99). Our study suggests for the first time that hookworm infection is associated with not only active TB but also LTBI.

Keywords: Kenya; Hookworm; Neglected tropical diseases; Latent mycobacterium tuberculosis

List of abbreviations

LTBI: Latent *Mycobacterium Tuberculosis* Infection; TB: Tuberculosis; STH: Soil-Transmitted Helminthiasis; BCG: Bacille de Calmette et Guérin; MCV: Mean Cell Volume; MCH: Mean Cell Hemoglobin; MCHC: Mean Cell Hemoglobin Concentration; PBMCs: Preparation of peripheral Blood Mononuclear Cells; ESAT-6: Early Secreted Antigenic Target 6 kDa protein; CFP10: 10kDa Culture Filtrate Protein; PPD: Purified Protein Derivative; ConA: Concanavalin A; IFN-γ: Interferon-γ; Th2: T helper 2; Th1: T helper 1; IL-10: Interleukin-10

Introduction

Tuberculosis (TB) is a disease caused by *Mycobacterium tuberculosis*, an acid-fast bacillus and is a serious threat for human health. In 2010, 8.8 million people newly developed TB and 1.1 million people died from TB [1]. After the infection is established, the majority (~95%) of individuals does not develop the disease, but instead maintain long-term latent infection. Five to 10 percent of asymptomatically infected persons develop TB during their lifetime by endogenous reactivation. Therefore, Latent *M. Tuberculosis* Infection (LTBI) is a major reservoir of the pathogen, and every effort thus should be made to diagnose LTBI to begin treatment of it in order to reduce TB burden [2].

Parasitic infections are common in TB endemic areas and are likely to impact on the high burden of TB [3]. Among parasitic infections, neglected tropical diseases caused by parasites, such as filariasis, onchocerciasis, schistosomiasis, and Soil-Transmitted Helminthiasis (STH), are still serious problem for human health. A high prevalence of STH and schistosomiasis are closely related to poverty, poor environmental hygiene, and lifestyle [4]. It is estimated that 1.4, 1, and 1.3 billion people globally suffer from *Ascaris lumbricoides*, *Trichuris trichiura*, and hookworm, respectively. Seven hundred twenty million people infected with STH are estimated to have clinical symptoms, and approximately 135,000 people die from complications per year [5]. Recent studies also suggest that chronic helminthic infection may reduce the efficacy of Bacille de Calmette et Guérin (BCG) vaccination, a live attenuated vaccine against TB [5,6]. Furthermore, regions with a high burden of helminthiasis are correlated with a high TB burden, implying that helminthic infection is a potential risk for TB development and vice versa [7]. However, the relationship between establishment of LTBI and each parasitic infection is unknown.

TB in children is public health problems with special significance, because children are more likely to progress life-threatening forms of the disease than adults. Besides, TB in children is a marker of recent transmission. However, information has been lacking about LTBI and
its risk among children in TB endemic area, so far. Kenya has a large and rising TB burden [8] and it ranks 13th among the 22 high-TB burden countries in the world. The incidence of TB in Kenya was reported as 29,800 per 100,000 people in 2010 by the World Bank report released in 2011. A high prevalence of other infectious diseases, including parasitic infections, has been reported in Kenya as well [9-11]. Mbita is located on the lakeshore of Lake Victoria, Nyanza province, Western Kenya and is endemic area of several life threatening infectious diseases. In this study, we investigated the relationship between LTBI and parasitic infection among school-aged children in Mbita, Kenya.

Materials and Methods

Ethical considerations

Study procedures followed were in accordance with the ethical standards of the Helsinki Declaration and approved by the Scientific Steering and Ethical Review Committees of the Kenya Medical Research Institute (SSC No. 2084). All data collection activities were careful explained, and parental consent was obtained from the district authority and other opinion leaders (health personnel and education officials), the headmasters, and the representatives of the pupils’ parents. Informed consent for the participation of children to the study was obtained from the parents/guardians. The consent form was written in English and translated into the local languages (Kiswahili and Luo) to obtain understanding for the study. Pupils whose parents/guardians had given consent were provided with an explanation of the data collection activities and were allowed to not participate or drop out of the study if they chose. The parents or guardians of the children enrolled in the study did not incur any cost for the transport or processing of the samples.

Study area, design and population

This cross-sectional study was conducted in Mbita district located around Lake Victoria in Nyanza Province, western Kenya. The population in Mbita district is 55,929 [12]. The study target population comprised primary school children in standard four, aged 9 to 19 years. There are 64 primary schools in Mbita district. The total number of school children in standard four in the year 2011 was 1,747 (859 males and 888 females, District Education office; described in research proposal SSC1088). About aqueous supplies, 84% of the household males and 88% females, District Education office; described in research proposal SSC1088). About aqueous supplies, 84% of the household

Cluster sampling was used with primary schools as the clusters. Prior to randomization, information on the number and size of the schools in the study area was obtained from the district education authority and entered in a computerized database. Information of the longitude and latitude of each school was added to the database using global positioning system hardware. Schools were ranked by geographical location to allow for equal distribution of the schools over the study area. Seven primary schools, including Kombe, Wanga, Nyawiya, Usungu, Ngodhe SDA, Wasaria, and Kamasengre, were randomly selected using R version 2.14.0 software. Pupils in standard four in the selected schools, whose parents/guardians agreed to the study, were enrolled in the study and assessed for BCG vaccination status and a history of ever being exposed to TB at home. Stool, urine and blood samples were collected from all registered individuals for diagnosis of the various infections.

Exclusion criteria

In this study, children were excluded if they did not complete an examination or the number of CD4-positive T cell counts was under 500 cells/ml. The reductions of CD4-positive T cell counts are more likely to indicate the infection of HIV.

BCG vaccine inoculation career

To know the status of previous vaccination with BCG, we checked the presence of BCG scars on the skins of the children.

Detection of intestinal helminthic infection

The children were appropriately instructed about the procedure for the collection of stool, after which they were given labeled specimen cups on the day before the test to collect stool in the next morning. The stool specimens for 3 consecutive days were transferred to a field lab and examined for hookworm eggs within an hour and intestinal helminthic infections by the Kato-Katz thick smear technique on the next day [13].

Detection of Intestinal Protozoan Infection

Intestinal protozoan infection was examined by the thin smear method using specimens collected as described above.

Detection of Plasmodium falciparum, P. malariae, P. ovale, and P. vivax

Plasmodium falciparum was identified by microscopic examination of a thin blood smear after staining with Giemsa. Four types of malaria parasites were distinguished by their morphological characteristics.

Measurement of hematological indicators

Blood samples were analyzed by using BM6050 (JEOL, Japan) to examine the amount of the hemoglobin, the number of red blood cells, and hematocrit. Mean Cell Volume (MCV), Cell Hemoglobin (MCH), and Cell Hemoglobin Concentration (MCHC) were calculated.

Detection of LTBI

PBMCs were purified from heparinized blood samples using BD Vacutainer cell preparation tubes (Becton, Dickinson and Company, Franklin Lakes, NJ USA 07417) according to the manufacturer’s instructions. After blood drawing and inversion, cell preparation tubes were centrifuged at 1,800 rcf for 20 min at room temperature. PBMCs were then collected, washed twice in Roswell Park Memorial Institute (RPMI) medium, and resuspended in 2.5 ml of RPMI medium containing 10% FCS and 50 µM 2-mercaptoethanol (RPMI complete medium).

M. tuberculosis infection was assessed by monitoring T cell responses to ESAT-6 and CFP10, which are produced by Mycobacterium avium-intracellular complex and BCG. We used overlapping synthetic peptides to detect T cell responses to ESAT6 and CFP10, because using these peptides can prevent the effect of nonspecific reactions due to contaminations of mitogens, such as LPS, and shorten the time to detect a reaction compared with use of recombinant proteins. The amino acid sequences of the synthetic peptides are as follows below.

ESAT-6 (1-20) (H-MTEQQWNFAGIEAAEASAIAQG-OH),
ESAT-6 (11-30) (H-IEAAASAIQGNTSIIHSLLD-OH),
ESAT-6 (21-40) (H-NVTSHSLDEGGQSLTKLA-OH),
ESAT-6 (31-50) (H-EGKQSLTLAAAWGGSGEA-OH),
ESAT-6 (41-60) (H-AAWGGSGSAEYQVQVQKWD-AH),
ESAT-6 (51-70) (H-YQVQVQKWDATTELNNALQ-OH),
ESAT-6 (61-80) (H-TATELNNALQNLARTISEAG-OH),
ESAT-6 (61-80) (H-TATELNNALQNLARTISEAG-OH),
ESAT-6 (61-80) (H-TATELNNALQNLARTISEAG-OH),
ESAT-6 (61-80) (H-TATELNNALQNLARTISEAG-OH),
ESAT-6 (61-80) (H-TATELNNALQNLARTISEAG-OH),
Many parasitic infections, including helminthiasis, are called neglected tropical diseases, which are specially endemic in low-income population in the developing countries but affect over one billion people [14]. The prevalence of hookworm infections, such as by *Ancylostoma duodenale* and *Necator americanus*, are estimated to

M. *tuberculosis*, but not from BCG vaccine strains or the majority of non-tuberculosis mycobacteria. By examining culture supernatants of PBMCs derived from 240 students, who did not show fever or prolonged cough over 2 weeks by a health assessment, we detected more than 125 pg/ml of IFN-γ in 191 children (79.6%) when their PBMCs were stimulated with PPD and more than 125 pg/ml of IFN-γ in 75 children (31.3%) when stimulated with ESAT-6 and CFP10 (39 females and 36 males) (Figure 1). All responders to ESAT-6 and CFP10 were included in the PPD responders. As predicted, BCG vaccination did not show a correlation with responses to ESAT6 and/or CFP10 (p=0.11). Based on these results, the students were assigned as individuals with LTBI when they did not show any symptom of TB and their PBMCs produced IFN-γ upon being stimulated with ESAT6 and CFP10.

We simultaneously assessed infections with various parasites. There were no differences among schools at the prevalence of protozoal and parasitic infection except for *S. mansoni*. Table 2 summarizes the number of students found to be positive for hookworm, *A. lumbricoides*, *T. trichiura*, *Schistosoma mansoni*, *Plasmidium falciparum*, *P. malariae*, *P. ovale*, *P. vivax*, *Entamoeba coli*, *E. histolytica/E. dispar/E. moshkovskii*, *Iodamoeba*, *Giardia intestinalis*, *Balantidium*, *Coccidia*, and *Blastocystis*.

The association between LTBI and other parasitic infections was examined using the Mann-Whitney U-test, the Wilcoxon rank sum test, and the chi-square test. We found a significant association between LTBI and hookworm infection (p=0.02). By contrast, we did not find any association between LTBI and other parasite infections. The p values for comparison between LTBI and each parasite infection were: p=0.61 for *A. lumbricoides*, p=0.02 for *T. trichiura*, p=0.30 for *S. mansoni*, p=0.16 for *P. falciparum*, p=0.50 for *P. malariae*, p=1.00 for *P. ovale*, p=1.00 for *P. vivax*, p=0.71 for *E. coli*, p=0.86 for *E. histolytica/E. dispers*. *E. moshkovskii*, *Iodamoeba*, *Giardia intestinalis*, *Balantidium*, *Coccidia*, and *Blastocystis* (Table 2).

The numbers of individuals positive for hookworm and LTBI are shown in Table 2 together with their odds ratios with 95% confidence intervals. The odds ratio of individuals infected with hookworm for LTBI was 3.019 times that in individuals without hookworm (95% confidence interval: 1.14-7.99), indicating a possible association between hookworm infection with LTBI among school children.

**Discussion**

In this study, 75 out of 240 (31.3 %) students were defined as LTBI among the students of standard 4 in Mbita, Kenya. Ten students were infected with hookworm out of 75 individuals with LTBI, while there were eight students with hookworm out of 165 individuals without LTBI. The odds ratio of hookworm infection in the LTBI population was 3.019 times as high as that in the non-LTBI population.

Many parasitic infections, including helminthiasis, are called neglected tropical diseases, which are specially endemic in low-income population in the developing countries but affect over one billion people [14]. The prevalence of hookworm infections, such as by *Ancylostoma duodenale* and *Necator americanus*, are estimated to

be frequent in developing countries, such as Asia, Africa, and Latin America, and approximately 740 million people are infected with these parasites in worldwide [14]. Infections with helminths, including hookworm, cause distinct immune responses. It is generally accepted that helminthic infection causes Th2 (Th2) immune responses. For example, Th2-dependent eosinophilic pneumonia is frequently observed after infection with a significant number of helminths, such as filaria, hookworm, or A. lumbricoides. However, some reports have shown that T helper 1 (Th1), rather than Th2 cytokines, are produced from PBMCs derived from hookworm-infected-individuals in endemic areas [15-17]. In endemic areas, people are frequently exposed to pathogens that induce a Th1 response before or after they are infected with helminths, which may be the reason why Th2 immune responses appear dampened, even in those co-infected with helminths. Infection with protozoa or bacteria that can stimulate a Th1 response results in suppression of the Th2 response induced by helminthic infection in mouse models [15,18,19].

On the other hand, it was reported that co-infection of both helminths and M. tuberculosis results in the suppression of IFN-γ production [20]. The Th2 response caused by hookworm infections may suppress a protective Th1 response against M. tuberculosis infection, and therefore, hookworm infection may allow the survival of M. tuberculosis and vice versa. Because we detected LTBI by measuring IFN-γ, an indicator of Th1 response, we cannot deny the possibility that LTBI-negative 8 children who infected with hookworm are false-negative for LTBI. Taking into account this possibility, our data indicates all the more significant association between LTBI and hookworm.

In our study, only hookworm infection was correlated with LTBI, in spite of the fact that other helminths, such as A. lumbricoides or T. trichiura, can evoke robust Th2 responses, as well as in the hookworm infection. In addition, we did not find the significant increase of the level of peripheral eosinophils, which are index of the Th2 immune response compared with those in uninfected children in this study. It is likely that the shift of an immune response from Th1 to Th2 caused by helminthic infections is not a sole reason to explain higher ratio of LTBI in hookworm-infected students.

Immunosuppressive T cells, such as regulatory T cells (Treg), suppress cellular immune responses through direct contact with immune effector cells and by the production of regulatory cytokines, including TGF-β and IL-10 [21,22]. It has been reported that hookworm infection causes induction of CD4⁺CD25⁺FOXP3⁺IL-10⁺ regulatory T cells [23] and repeated infection with hookworm stimulates production of high levels of IL-10 [24], which inhibits host protective immunity against M. tuberculosis. Accordingly, there is a possibility that hookworm-induced IL-10 impacts on the sensibility to M. tuberculosis infection.

It is generally known that iron-deficiency anemia is caused by heavy infection with adult hookworms in the intestinal tract. It is estimated that 36 million out of 1,300 million people infected with hookworm have iron-deficiency anemia, and 65,000 people annually die from hookworm-induced anemia. Iron-deficiency anemia is a typical symptom observed in individuals heavily infected with hookworm, but rarely seen in those with other helminths. Iron status also affects TB disease; for example, iron overload is reported to be a risk for TB progression [25]. In this study, the MCV and MCHC of the students, which are indicators of iron-deficiency anemia, were lower than the standard values generally, but there was no difference between hookworm-infected and non-infected children (MCV: p=0.35; MCHC: p=0.47), and there was no difference in iron status between responders to ESAT6 and/or CFP10 and non-responders (p=0.16). Accordingly we did not observe obvious effects of anemia caused by helminth infection on the establishment of LTBI in this study.

The current study found that hookworm infection was associated with LTBI. As discussed above, the exact reason of this finding is unclear. In mice model, recent report showed that Mycobacterium-specific both Th1 and Th17 cells by hookworm infection enhances establishment of LTBI [26], supporting our human study. We consider that next studies should examine whether this association can be observed in other areas and adults as well. Addictively, the studies should be conducted to examine whether hookworm infection causes expansion of the LTBI population and/or directly contributes to TB progression in addition to establishment of infection because there are several reports indicating that helminthic infection is a risk factor for developing TB [27-29]. Our study suggests the necessity of the deep studies to understand the relationship between M. tuberculosis and hookworm infection on the prevalence and progression of disease in high-burden countries, including tropical and subtropical areas.
