Introduction

The respiratory system is constantly exposed to environmental pathogens and toxins, spread as aerosol in the environment. The mucociliary system is the first defense of airways against harmful particles and disruptive environmental triggers. Ingredients, bacteria and respiratory viruses are trapped by airways’ mucosa and driven to the larynx by respiratory beats, ultimately egress due to swallowing or coughing [1]. Airways’ clearance by the mucociliary system is the main host defense mechanism of upper or lower respiratory tracks. Defects in this process, either genetically or acquired, make an individual susceptible to contracting chronic nasal, paranasal sinuses’ and airways’ tracks chronic infections [2]. Nose is the major part of the respiratory system that transfers air into and out of the system, playing an important role in providing necessary humidity (100%) and playing an important role in providing necessary humidity (100%) and temperature (37 degrees), local defense and filtration of ingredients and gases [3]. A variety of factors affect mucociliary clearance such as increasing age, smoking, chronic nasal and pulmonary diseases (rhinitis, asthma, bronchiectasis, and chronic obstructive pulmonary disease), and anatomical defects of the upper respiratory tract (septal deviation, hypertrophy of the concha, etc.) and a history of nasal surgery or trauma. The role of defects in mucociliary function due to either genetic diseases (cystic fibrosis) or acquired (secondary to infection of erosive mucociliary system diseases) has been recognized in many chronic airways tracks’ diseases [4]. For example, defects in one or more parts of mucociliary clearance (epithelium, mucosa and cilia) cause chronic rhinosinusitis and stasis rinosinusial discharges lead to chronic inflammations [5].  

Results of these tests are dependent on individual factors which are directly related to mucociliary clearance. Verifying the consistency between nasal mucociliary clearance and tracheobronchial tracks suggests qualification of mucociliary clearance by less invasive methods like the saccharin test.

Methods

This study was reviewed and approved by the Institutional Review Board at the Iran University of Medical Sciences, and written informed consent was obtained from all participants. Volunteers enrolled in this clinical trial were scheduled to receive the NAC or the placebo and do STT before and after it in Firoozgar general hospital, Tehran, Iran, from January 2012 to March 2012. All individuals were divided into case and control groups by double-blind method.

The Effects of N-Acetyl Cysteine on Nasal Mucociliary Clearance in Healthy Volunteers: A Randomized, Double-Blind and Placebo-Controlled Study

Abstract

Background: Mucociliary clearance is an important host defense function of the upper respiratory tract that requires the coordinated beating of cilia and results in the transport of mucus to the oropharynx. N-Acetyl Cysteine is a mucolytic drug currently used in pulmonary diseases. In the present study we sought to assess the effects of N-Acetyl Cysteine nasal mucociliary clearance in healthy volunteers.

Methods: A total of 100 healthy individuals (55 male) with the mean age of 34.21 (± 12.63) years were included in the present randomized, double-blind and placebo-controlled study. Participants were assigned into two groups of case and control. The Mucociliary Clearance Time (MCT) was measured by saccharine test; measuring the time in minutes required for the subject to taste a saccharin particle placed on the inferior turbinate of the nasal. The variables studied were nasal MCT before and after taking the placebo or NAC, age, and sex. Data were analyzed using SPSS V.16.

Results: Wilcoxon signed ranks test demonstrated considerable different of Saccharine Test Time (STT) between before and after taking the NAC (p=0.021), and no significant different of STT between before and after taking the placebo (p=0.723).

Conclusion: N-Acetyl Cysteine exerts measurable effect on nasal mucociliary clearance in healthy volunteers; therefore may be beneficial in conditions associated with disruption of mucociliary clearance such as rhinitis and sinusitis. However, further studies are suggested to achieve more conclusive results.

Keywords: Mucociliary clearance; N-Acetyl cysteine; Saccharin test

The Effects of N-Acetyl Cysteine on Nasal Mucociliary Clearance in Healthy Volunteers: A Randomized, Double-Blind and Placebo-Controlled Study

A total of 100 healthy volunteers (55 males and 45 females) with a mean age of 34.21 ± 12.63 y/o (ranging from 19 to 86) were included. Range of age for 71% of volunteers was 21-40 y/o, along with 3% under 20 and 3% above 60. The control group consisted of 24 men (48%) and 26 women (52%) with a mean age of 33.72 ± 14.40 y/o (ranging from 18 to 86), resulting in a normal distribution. The case group consisted of 31 men (62%) and 19 women (38%) with a mean age of 34.58 ± 14.75 y/o (ranging from 27 to 58). Although the median was 28.5 and had long distance to end of range (86 y/o), distribution of age data was not normal. Despite the mean age, the mean gender of the control group has a normal distribution, but the case group does not (Figure 1).

136 volunteers (double the required individuals) were selected to participate in the study, where 36 volunteers were excluded. The exclusion criteria consisted of any anatomical defects of the upper respiratory system (septal deviation, hypertrophy concha, etc.), history of nasal surgery or trauma, history of chronic nasal and respiratory diseases (asthma, rhinitis, chronic obstructive pulmonary disease, nasal polyps), acute infection of respiratory diseases during the recent six weeks, gustatory defects, history of smoking or use of drug (“nonsmoker” was defined as a person who has never smoked or has given up smoking for five years), pregnancy and history of taking drugs that influence mucociliary clearance, such as antihistamines, adrenergic drugs, anticholinergic drugs, local and systemic anticongestants, mucolytics, corticosteroids and theophyllin.

The saccharin test was based on Anderson et al. method in 1974 [8]. Saccharin test was done for every individual before taking medication of the NAC or the placebo. Individuals did not need any preparation for STT. For each test, 50 mg of saccharin powder, made by Merk Company, was placed on inferior turbinate, 1 cm away from the tip. Since maximum dose of saccharin is 2.5 mg per kg per day, the amount used in this study was safe for the subjects. The researcher made sure saccharin was precisely located on mucosa, avoiding squamous cell epithelium. All the individuals were in sitting position, bending their heads slightly backwards and breathed normally. All individuals were asked to inform the researcher of sensing any new taste in their pharynx, where they were not aware of the sweet taste of saccharin to prevent false positives. Time measurements were done before and after taking NAC or the placebo. The highest NAC concentration in the mucosa is detected within 2-4 hours. The taste of saccharin powder requires 12-15 hours to be eliminated from the nasopharynx cavity, and doing the second saccharin test sooner than 15 hours could have interfered with the first one. As a result, the test was repeated after 18 hours to avoid overlaps and time measurements were done before and after taking NAC or the placebo.

Data analysis was completed using Statistical Package for Social Sciences version 16 software. For each measured variable, descriptive values are expressed as the mean-standard deviation. Analysis of quantitative variables was done using Wilcoxon signed ranked test. Categorical variables were compared using the Chi square test and relationships were assessed by Pearson. Reported p values are 2-tailed and p<0.05 is considered statistically significant.

**Results**

The mean Saccharin Test Time (STT) before taking the placebo or NAC in all 100 volunteers was 9'13'' (ranging from 3:00'' to 14:00''). The time of sensing sweetness of saccharin in the control group before taking the placebo was 10'45'' ± 7'13'' (ranging from 2:00'' to 14'00''), where the mean time of distinguishing saccharin taste in the control group after taking the placebo was 11'05'' ± 7'46'' (ranging from 1'30'' to 17'00''). So, the mean time of the control group before and after showed only a 00:20'' difference. In Wilcoxon Signed Ranks test of the control group, there were 3 individuals (6%) among 50 with no fluxion, 23 (46%) with negative fluxion and 24 (48%) with positive fluxion.

The mean time of sensing sweetness of saccharin in the case group before taking the NAC was 9'13'' (ranging from 3:00 '' to '14:00''), where the mean time of distinguishing saccharin taste in the case group after taking the NAC was 8'07'' (ranging from 1'00'' to 15'00''). Therefore, the mean time of case group before and after taking NAC demonstrated a 00:44'' difference. Wilcoxon Signed Ranks in case group showed 1 individual (2%) among 50 with no fluxion, 14 (28%) with negative fluxion and 35 (70%) with positive fluxion. There was no relationship between the age and the difference STT before and after taking the placebo and NAC in all 100 volunteers, where related analysis indicated 0.95% assurance (p=0.503) (Figure 2). There was no relationship between the age and the difference of STT before and after taking the placebo in control group (0.95% assurance (p=0.463)), as well as NAC in the case group (0.95% assurance (p=0.309)). There was no relationship between the genders and the difference of STT before and after taking the placebo in control group and NAC in the 100 volunteers, where related analysis showed 0.95% assurance (p=0.153). There was no relationship between the genders and the difference of STT before and after taking the placebo in the control group, as well as NAC in case group with 0.95% assurance ( p=0.271 and p=0.672, respectively).

**Discussion**

Respiratory system is tremendously resistant to environmental triggers in spite of being exposed to many types of pathogens and toxic chemical substances. Respiratory mucosa provides this highly effective defense by trapping inspiratory and removing toxic ingredients from lungs using cilia movements, cilia beats and coughing [9]. Mucous is produced and excreted constantly where mucosa cilia frequency of 12-15 beats per minute rate is ensures clearance of mucosa layers at rate of one millimeter per minute [10]. The rate of clearance is increased by hydration, as well as higher rate of cilia beats due to adrenergic, cholinergic and adenosine agonist drugs [10,11]. Examination of
mucociliary clearance can aid in screening respiratory diseases, where early diagnosis of low mucociliary function can result in faster and more effective treatments [12]. Studies have shown that using substances such as saccharin and aspartame for testing is easy to implement and analyze, without requiring complex equipments or causing discomfort for patients [13-15]. In current study saccharine test was used to evaluate the effect of NAC on mucociliary system. Maximum time of sensing sweet taste (14’00”) was shorter than that reported by Rev med study (36’00”) [16] which is explained by race and genetic differences as well as volunteers’ younger age of the current study. Previous studies reported a meaningful relationship between demographic variants (age and gender) and saccharin test time [15,16]. In the current study, there was no relationship between age and the mean STT because there was no normal age distribution by chance. We can improve this error by bigger sample size (Figure 3).

Difference of 00:20” between the mean times of the control group before and after application of placebo indicates lack of distinction between them which was confirmed by Wilcoxon Signed Ranks. 48% of individuals who took the placebo sensed the saccharin taste sooner than the first time due to individuals’ autosuggestion. There is no statistical relationship between these variants with 95% assurance (p=0.723). The mean times of case group before and after taking NAC showed a 00:54” difference, with a positive fluxion nearly three-fold compared to the control group. There was also a significant difference between STT before and after taking the NAC with 95% assurance (p=0.021), confirming the positive impact of NAC on nasal mucociliary clearance.

**Conclusion**

We conclude that N-acetyl Cysteine exerts measurable effect on nasal mucociliary clearance in healthy volunteers and therefore is beneficial in conditions associated with disruption of mucociliary clearance such as rhinitis and sinusitis diseases as much as pulmonary diseases as an adjuvant.
