The Gastric Precancerous Cascade

Abstract

Although most gastric cancers are first detected after the fifth decade of life, they represent the end product of a prolonged precancerous process initiated during childhood as a consequence of the infection of the mucosa with Helicobacter pylori. The initial phase of the process consists of active non-atrophic gastritis. The following stages are: multifocal atrophic gastritis, intestinal metaplasia (initially of complete type, then incomplete type), dysplasia and finally invasive carcinoma. The progression of the lesions is modulated by other factors such as the diet: excessive salt intake accelerates the process while fresh fruits and vegetables play a protective role. In addition, the geographic location influences the process. In Colombia, high altitude Andes mountain dwellers display more advanced lesions than the residents of the Pacific coast. It appears that the ancestral origin of the infecting Helicobacter pylori strains have a determining influence on their capacity to induce precancerous lesions. The Helicobacter pylori strains infecting the mountain dwellers are of predominantly European phylogeographic origin. The Helicobacter pylori strains infecting the Pacific coast dwellers are predominantly of African origin, probably less virulent. Chemoprevention trials have been partially effective, when the precancerous lesions are not too advanced. Such trials may not eliminate the infection but have a tendency to eliminate preferentially the most virulent bacterial strains.

Keywords: Gastric Precancerous Lesions; Gastric Cancer; Gastric Adenocarcinoma; Helicobacter pylori; Gastric Atrophy; Multifocal Atrophic Gastritis; Intestinal Metaplasia; Dysplasia; Surveillance

Abbreviations: CAG PAI: Cytotoxin-Associated Gene Pathogenicity Island; IM- Intestinal Metaplasia; PG- Pepsinogen; SPEM- Spasmolytic Polypeptide Expressing Metaplasia

Introduction

Although gastric cancer incidence and mortality rates have been slowly declining during the last six decades in many countries, this cancer is still a major health burden worldwide. Gastric cancer represents the second most frequent cause of cancer-related deaths and ranks 4th in cancer incidence [1]. More than 95% of gastric cancer cases are adenocarcinoma, which were classified mainly into intestinal and diffuse types by Lauren and Jarvi, two Finnish pathologists who also proposed that at least half of the gastric carcinomas originate in islands of intestinal epithelium in the gastric mucosa [2,3]. Further observations led to propose that gastric adenocarcinoma of the intestinal type is the final stage of a decades-long inflammatory process characterized by a series of histological changes in the gastric mucosa, as follows: non-atrophic gastritis → multifocal atrophic gastritis without intestinal metaplasia → intestinal metaplasia, complete type → intestinal metaplasia, incomplete type → dysplasia → adenocarcinoma [4,5]. This precancerous sequence is triggered by the infection with Helicobacter pylori (H. pylori), which usually occurs during childhood in developing countries [6-8]. It has been estimated that 5.5% of the total number of cancer cases and 63% of gastric cancer cases worldwide are attributable to Helicobacter pylori infection [9]. For this reason, gastric cancer is considered an infectious disease. There is a wide variety of factors that may interact to determine the outcome of H. pylori infection and the rate of progression of precancerous lesions, including H. pylori virulence, host responses and environmental and dietary factors.

Multiple studies have demonstrated that populations at higher risk of gastric cancer have higher prevalence of precancerous lesions [10-12]. Likewise, patients with premalignant gastric lesions are at considerable risk of gastric cancer. A large study including 92,250 subjects with premalignant gastric lesions at baseline showed that within 1, 5, and 10 years of follow-up after initial diagnosis, gastric cancer was diagnosed in 0.3%, 0.6%, and 0.8% of patients with atrophic gastritis; 0.7%, 1.2 %, and 1.8% of patients with intestinal metaplasia; 2.1%, 3.1%, and 3.9% of patients with mild-to-moderate dysplasia; and 24.9%, 29.5%, and 32.7% of patients with severe dysplasia [13].

The Infectious Agent

The main recognized etiologic factor for gastritis, peptic ulcers and gastric cancer is H. pylori, a bacterium that infects the gastric mucosa of more than half of the world’s population, with higher prevalence rates in the developing world [9]. The isolation of H. pylori for the first time in 1982 and the identification of its role in causing gastritis and peptic ulcers was achieved in Australia by Marshall and Warren [14], who were awarded the Nobel Prize in 2005 for their discovery. Several studies then associated the development of gastric cancer with the H. pylori infection [15-17] and in 1994 the international Agency for Research in Cancer recognized the infection with H. pylori as a type I human carcinogen [18].

H. pylori are a spiral, gram-negative bacterium equipped with a series of mechanisms that guarantee its survival within the acid gastric niche. H. pylori strains have an extraordinary genetic diversity [19] which partially explains the fact that less than 1% of people infected with H. pylori will ever develop gastric cancer. There are multiple recognized H. pylori virulence factors, including cagA, vacA, babA2, icaA and sabA [20-22]. Probably the most extensively studied virulence determinant is the Cytotoxin-Associated Gene Pathogenicity Island (cag PAI). One of the genes within the cag PAI encodes CagA, an oncprotein that is Trans located into host epithelial cells by a type IV secretion system [23,24]. CagA interacts with numerous intracellular effectors resulting in pro inflammatory and mitogenic responses, disruption of cell-cell

junctitions, loss of cell polarity, and morphologic transformation of the epithelial cells [20]. In addition, H pylori CagA induces the production of the enzyme spermine oxidase, which induces oxidative damage in epithelial cells, creating a subpopulation of cells that are resistant to apoptosis and thus at high risk for malignant transformation [25]. Subjects infected with strains that contain the cagA gene are associated with more severe gastric pathology and gastric adenocarcinoma than subjects infected with cagA-negative strains [26-29]. It is estimated that the cag PAI is present in approximately 60-70% of Western H. pylori strains and virtually 100% of East-Asian H. pylori strains [30]. In Colombia, a country with high incidence of gastric cancer, it is estimated that more than 80% of the adult population is infected with H. pylori and 70-80% of the strains obtained from symptomatic patients are cagA-positive [31,32].

Despite somewhat contradictory results and an unexplained biologic mechanism, blood group A has been considered a risk factor for gastric cancer. A recent study in Venezuela found that in carriers of cagA-positive H. pylori strains an increased risk of intestinal metaplasia and dysplasia was associated with blood group A [33].

Besides the mentioned virulence determinants, the phylogeographic origin of the H. pylori strains seems to play a role in the presence and severity of gastric precancerous lesions. Multilocus sequence typing of seven housekeeping genes was used to identify the ancestral origin of 64 cagA-positive H. pylori isolates from two populations in Colombia with contrasting gastric cancer risks. In the southern state of Nariño, the inhabitants of Tuquerres in the Andes Mountains (3,000 meters above the sea level), are predominately of Amerindian extraction and have an elevated risk of gastric cancer. The town of Tumaco, on the Pacific coast and approximately 200 kilometers from Tuquerres, is inhabited by African descendants that have a low risk of gastric cancer. All H. pylori isolates from the habitants of the mountains displayed a predominantly European phylogeographic origin. By contrast, two thirds of the H. pylori isolates from African descendants living on the coast displayed predominantly African origin and one third displayed European origin. Overall, subjects carrying H. pylori strains of European origin showed more advanced gastric precancerous lesions and greater oxidative damage in the gastric mucosa than subjects harboring strains of African genotype [34]. Further studies revealed that Colombian strains of European phylogeographic origin expressed higher levels of the oncoprotein CagA than did strains of African origin [35] and a bacterial DNA motif was associated with more advanced precancerous lesions [35].

It is important to note that retrospective studies on the risk of gastric cancer in relation to H. pylori infection underestimate the true risk, due to loss of the infection with the onset of precancerous lesions. H. pylori usually do not colonize gastric mucosa with intestinal metaplasia, dysplasia or cancer, and there is evidence that with the development of advanced gastric lesions the organism can be lost from the stomach (Figure 1).

The Gastric Precancerous Cascade

The stages of the precancerous cascade for gastric adenocarcinoma are a series of histologically recognizable changes in the gastric mucosa that follow the sequence: non-atrophic gastritis, multifocal atrophic gastritis, complete intestinal metaplasia, incomplete intestinal metaplasia, and dysplasia. Long-term observations in populations at high risk of gastric cancer have shown that this process may take decades before malignant transformation is observed [36,37]. The gastric mucosa in patients with gastric adenocarcinoma frequently shows the presence of all the steps in this cascade.

Non-atrophic gastritis H. pylori infection is the most common condition causing chronic gastritis. Upon colonization of the gastric mucosa, H. pylori elicit an acute and chronic inflammatory response characterized by infiltration of polymorph nuclear neutrophils and mononuclear cells, predominantly lymphocytes and plasma cells in the lamina propria. The term “active gastritis” is used to denote the presence of neutrophils, which is a very sensitive marker of the presence of H. pylori. Lymphoid aggregates with germinal centers are frequently observed and are considered characteristic of H. pylori-induced chronic gastritis (Figure 2). Other histological changes include intraepithelial neutrophilic or lymphocytic infiltrate, pit abscesses, mucus depletion, epithelial detachment, and foveolar hyperplasia. When H. pylori is eradicated, the neutrophilic infiltrate disappears within days but the chronic infiltrate may remain for months or years [38]. The Updated Sydney System for the classification of gastritis has been a useful tool for the understanding between pathologists and gastroenterologists. This classification combines topographical, morphological and etiological information for non-atrophic and atrophic (non-metaplastic and metaplastic) gastritis and provides a visual scale for grading of histological variables [38].

Multifocal atrophic gastritis Prolonged and severe chronic active...
inflammation may lead to permanent damage of epithelial cells and subsequent loss of glands (atrophy). In addition, as a result of the sustained inflammatory process, deposit of fibrous tissue may be observed in the lamina propria (Figure 3A). Because *H. pylori* colonize initially the gastric antrum, both inflammatory and atrophic changes are initially and more frequently observed in the antral mucosa. Over time, the bacterium may disseminate proximally to the oxyntic mucosa, sometimes favored by the decrease in gastric acid secretion caused by the use of proton pump inhibitors. *H. pylori* colonization and its subsequent inflammatory process in the oxyntic mucosa may result in loss of parietal and chief cells, which are frequently replaced by cells with mucous phenotype similar to antro pyloric epithelial cells. This lesion is called pseudopyloric metaplasia or Spasmolytic Polypeptide Expressing Metaplasia (SPEM) (Figure 3B). In pseudopyloric metaplasia the number of glands may not be reduced, but the loss of native glandular epithelium is considered an atrophic change. Recent evidence supports the importance of pseudopyloric metaplasia in gastric carcinogenesis (through Tran’s differentiation from mature chief cells following parietal cell loss) [39,40]. The loss of native glandular epithelium is usually observed in multiple small foci, which are more frequently found along the lesser curvature of the stomach, but over time they may be scattered throughout the entire mucosa.

Intestinal Metaplasia (IM) is the replacement of gastric epithelium with epithelium displaying intestinal phenotypes, implying adaptation to environmental stimuli.

Identified risk factors for IM include *H. pylori* infection, high salt intake, smoking, alcohol consumption, and chronic bile reflux [41–45]. It is not clear how metaplastic cells emerge, or what cell they emerge from, but the new cell type is presumably better suited to withstand the altered environment. IM usually develops in islands within areas of chronic atrophic gastritis, more frequently along the lesser curvature of the stomach. Over time, the metaplastic foci increase in size and may coalesce, covering large areas of antral and oxyntic mucosa. The prevalence of IM increases with advanced age [11,36,46].

IM is classified into two main types: complete (type I or small intestinal) and incomplete (types II and III, or colonic) [47]. Complete IM is characterized by the presence of mature goblet cells, alternating with enterocytes that display well-developed brush border (microvilli). Paneth cells may be observed, usually at the bottom of the glands (Figure 4A). Sialomucins are observed in goblet cells and enterocytes do not show any mucin content. Complete IM is the most frequently observed type in gastric biopsies and is the type that carries the lowest risk of gastric cancer.

Incomplete IM is characterized by presence of columnar mucous and goblet cells in various stages of differentiation displaying mucus vacuoles of different sizes, and by absence of absorptive cells (Figure 4B). Incomplete IM may display mild to moderate alteration of the glandular architecture, and is frequently found mixed with complete
IM. Incomplete IM is sub classified into types II and III according to the type of mucin expressed [47]. In type II, neutral and Sialomucins are expressed in column arc ells, and Sialomucins in goblet cells. Type III expresses predominantly sulfomucins in columnar cells and sialo- or sulfomucins in goblet cells.

Multiple studies have demonstrated that the incomplete type of IM, especially the type III [47-53] and the extension of the metaplastic changes [48, 54-56] are associated with higher risk of progression to gastric cancer. Furthermore, a strong correlation has been documented between IM extension and IM type, with incomplete or type III IM occurring more frequently among more extensive metaplastic lesions [48, 56]. In addition, on the basis of quantitative morphometric analyses, it has been observed that type III IM may be classified as low-grade dysplasia [57].

It is not clear to what extent the metaplastic changes can be reversed if the normal cellular environment is restored, but it does not seem to happen frequently, especially when the metaplastic changes are extensive.

Dysplasia (synonyms: intra epithelial neoplasia, non-invasive neoplasia). Dysplasia in the stomach is a term to define architectural and cytological abnormalities of the epithelium that are considered an intermediate step between no neoplasia and invasive neoplasia. Dysplastic lesions are usually observed arising in areas of IM, especially of the incomplete type, and also surrounding adenocarcinoma. Only a small fraction of individuals with IM develops dysplasia.

Multiple systems of classification for dysplasia have been developed. The Padova international classification [58] was proposed to facilitate the communication between pathologists and clinicians and for a better understanding among pathologists around the world. The term non-invasive neoplasia was introduced in this classification to replace the term dysplasia. The categories proposed were: 1) negative for dysplasia, 2) indefinite for dysplasia, 3) non-invasive neoplasia (sub classified into low grade and high grade), 4) suspicious for invasive carcinoma, and 5) invasive adenocarcinoma. Shortly after, another system was developed: the Vienna classification of gastrointestinal epithelial neoplasia. In this system and its subsequent modified version, a nomenclature was proposed to be used not only for gastric dysplasia but also for esophageal and colonic dysplastic lesions [59]. More recently, the classification of the World Health Organization recommends the term slow-grade and high-grade intra epithelial neoplasia/dysplasia [60].

The term “indefinite for dysplasia” is used in the presence of atypical lesions of the gastric mucosa in which the pathologist cannot differentiate with certainty between reactive epithelial changes and dysplasia. It is a temporary diagnosis and a follow-up including a new endoscopic procedure and biopsy sampling should be scheduled. Low-grade dysplasia is characterized by crowded tubular glands lined by column arc ells displaying elongated, hyper chromatic and pseudo stratified nuclei, with cigar-like appearance. The nuclei preserve their basal orientation and polarity. The dysplastic epithelium shows little or no mucin secretion. There is loss of interglandular stroma displaying back to back orientation (Figure 5A). In high-grade dysplasia, the architectural changes become prominent, showing irregular glands with budding and branching. Intraluminal folding of the dysplastic epithelium may develop into complex forms such as cribriform pattern. Cytologically, the nuclei are larger and show rounded shape rather than the cigar-shaped nuclei seen in low-grade dysplasia. Prominent nucleoli are observed and the basal nuclear orientation is lost (Figure 5B). Mitotic figures are frequent and atypical forms may be present. The dysplastic epithelium is confined to the epithelial compartment and there is no evidence of invasion through the basement membrane into the lamina propria. Disagreement between Japanese and Western pathologists is present in this category [61]. For Western pathologists invasion to the lamina propria or beyond is the hallmark of adenocarcinoma (Figure 6). For Japanese pathologists definitive neoplastic epithelium, even in the absence of proven invasion, are grounds for a diagnosis of adenocarcinoma.

**Management of Gastric Precancerous Lesions**

Under current standards, it is advisable to eradicate *H. pylori* infection in any patient with gastritis with or without precancerous...
IM to dysplasia and carcinoma is an -independent process. H. Pylori eradication may have little or no beneficial effect in prevention of gastric gastritis without IM. In patients with extensive IM or dysplasia, the eradication is greater in subjects with non-atrophic gastritis or atrophic H. pylori by this bacterium [62-69]. However, the beneficial effect of mucosal inflammation and by reversing molecular events induced effect on progression to gastric cancer by reducing or eliminating lesions. Evidence supports that eradication of H. pylori has a preventive effect on progression to gastric cancer by reducing or eliminating mucosal inflammation and by reversing molecular events induced by this bacterium [62-69]. However, the beneficial effect of H. pylori eradication is greater in subjects with non-atrophic gastritis or atrophic gastritis without IM. In patients with extensive IM or dysplasia, the eradication may have little or no beneficial effect in prevention of gastric cancer [70, 71]. Ample evidence suggests that the progression from IM to dysplasia and carcinoma is an H. Pylori-independent process. However, the reduced colonization density in the gastric mucosa with such lesions may impair the sensitivity of histology, culture, and urea breath test for the detection of the bacterium. Although H. pylori are generally absent from areas of complete IM, there are a small percentage of cases with incomplete IM that show adherence of the bacterium to the metaplastic epithelium [72, 73].

Large-scale H. pylori eradication as a preventive measure for gastric cancer has been the object of controversy. This measure is not recommended due to the possibility of appearance of antimicrobial-resistant strains, not only H. pylori but other bacteria as well. In addition, virtually all treatment schemes present some margin of failure and the reinfection/recrudescence rates are often high. Moreover, since H. pylori has accompanied human beings since ancient times [74], strong arguments exist that consider this bacterium as part of the human gastric microbiome and its elimination as the cause of the increase in prevalence of diseases such as gastro esophageal reflux, Barrett’s esophagus, and esophageal and cardiac adenocarcinoma [75].

Besides eradicating the infection, the clinical management of patients with precancerous gastric lesions is controversial and the guidelines are still evolving. The identification and surveillance of patients at high risk of progressing to gastric cancer represents the most effective way of reducing the burden of this disease. Subjects at the highest risk are those with: 1) Extensive atrophic gastritis and/or IM, 2) Presence of incomplete type IM (usually found in a background of extensive IM), 3) Dysplasia, including “indefinite for dysplasia”, 4) Family history of gastric cancer. Additional risk factors to consider are: history of tobacco smoking, ethnicity (Hispanics, African Americans, Asians, and Native Americans in the United States are at higher risk) and origin of the patient in a geographic area with high risk of gastric cancer.

To assess the extension of the atrophic (non-metaplastic and metaplastic) changes in a patient with diagnosis of atrophy or IM in a pathology report, accepted guidelines recommend sampling of the gastric mucosa as follows: antrum (two biopsy samples), incisura angularis (at least one sample), and corpus mucosa (two samples) [38,76]. Two systems have been proposed to classify the risk of gastric cancer based on histological scoring of the extension of atrophic-metaplastic lesions: 1) Operative Link On Gastritis Assessment (OLGA) which includes scoring of non-metaplastic atrophy, pseudopyloric metaplasia and IM [76], and 2) Operative Link On Gastric Intestinal Metaplasia Assessment (OLGIM) [77], which only scores extension of IM. Both systems classify the risk of cancer into stages 0 to 1V, and consider that patients in stages III and IV are at high risk and should enter surveillance programs for gastric cancer prevention. Both systems ignore the type of IM as a risk factor, although a later study reported a strong association between incomplete IM and the high-risk OLGA stages [78].

In 2012, a consensus on guidelines for the management of precancerous gastric lesions [79] recommended taking “at least four biopsies of the proximal and distal stomach, on the lesser and greater curvatures” using magnification chromoendoscopy or narrow-band imaging endoscopy for proper evaluation of the lesions. Besides the fact that these tools for endoscopy are time-consuming, costly, and not widely available in clinical practice, their actual benefit for improving diagnosis of gastric atrophy and intestinal metaplasia are mains to be consistently proved. In addition, these guidelines do not emphasize sampling the incisura angularis, which is widely considered necessary [38,76,80,81].
The above mentioned consensus guidelines recommend that patients with extensive atrophy and/or extensive IM should be followed-up with endoscopy every three years and that those with mild to moderate atrophy and/or intestinal metaplasia limited to the antrum do not need follow-up [79]. Controversy exists regarding these recommendations. First, it has been questioned that the same recommendations be applied to patients with either non-metaplastic atrophic gastritis or IM, since these two lesions show different risks of progression to cancer [81]. Second, due to the poor survival of gastric cancer in the Western world and to the fact that most of these tumors are diagnosed in an advanced stage, it has been proposed that subjects with IM that have an additional risk factor for gastric cancer should be followed with annual endoscopy [81, 82]. In the remaining patients with IM, a less intensive surveillance (every 2-3 years) has been proposed [81, 82].

The presence of dysplasia is an indicator of high risk for gastric cancer and it should be confirmed and classified by two gastrointestinal pathologists, due to the high inter-observer variability. The management of gastric dysplasia is also a matter of current debate and several approaches have been used/proposed [79]. However, the finding of dysplasia of any grade in a non targeted biopsy sample must be followed-up immediately (with endoscopy and extensive mapping) and between 6 and 12 months later to rule out a coexisting gastric cancer missed at the initial endoscopy. If there is dysplasia with a visible lesion at endoscopy, it should be classified according to stage and resection of the lesion must be carried out [79].

Non-invasive screening tests that can be applied to large populations to assess cancer risk or detect early gastric cancer cases are needed. In Japan and Korea, where gastric cancer is highly prevalent, national programs for mass screening and early detection exist. In Japan, a 40 to 60% decrease in gastric cancer mortality has been observed in cases detected under screening programs. Serum Pepsinogen (PG) levels have shown some potential for establishing the extent of gastric atrophy in various populations. PGI is secreted only in the oxyntic mucosa, and PGII is secreted in both oxyntic and antro pyloric mucosa. In the presence of atrophy of the oxyntic mucosa, there may be decrease in both PGI and PGII, but PGII usually shows a more marked decrease. In Japan, severe gastric atrophy is diagnosed when serum PGI levels are <70 µg/l and a PGI/PGII ratio<3; these levels have proven useful both PGI and PGII, but PGI usually shows a more marked decrease. The combination of PG serum levels and H. pylori serology has also demonstrated to be useful in gastric cancer risk stratification in some populations. However, multiple studies around the world have shown inconsistent results for the validity of the serum PG levels on the detection of precancerous lesions. Sensitivity values ranging from 9 and 92% and specificities between 10 and 100% have been found for the detection of gastric corpus atrophy [79]. Similarly, sensitivity values between 15 and 75% have been reported for the detection of IM [79]. The use of different methods for PG levels assessment, different cutoff values, and variable endoscopic biopsy protocols for histological diagnosis makes it difficult to compare studies. Other serological markers for the detection of precancerous gastric lesions such as trefoil factor 3, hypermethylation of genes and micro RNAs are subject of current investigation.
